Operation on a Calcified Epithelioma; Recurrence.—Reverdin has operated on a calcified epithelioma. The tumor consisted of hard, round nodules, surrounded by masses of tissue which was hard, but not calcified. The tumor recurred. This growth, which is quite rare, generally develops before the age of thirty years, especially in the region of the eyebrows and eyelids. Some authorities think these tumors related to sebaceous cysts. Some believe them to be endotheliomatous. It is probable that the origin of the tumor is an ectodermic inclusion, it may be embryonic, it may be traumatic.—*Le Bulletin Médical*, October 30, 1901.

A New Contribution to the Study of Diplobacillary Conjunctivitis. Aug. Collomb has given careful study to this subject. In the young infant, this affection has been rarely found. The contagion of the diplobacillary infection has been proved by inoculations in man. A little of the pure culture placed on a human conjunctiva, which up to this time has been perfectly healthy, is sufficient to produce the typical affection. Epidemics in families are most common. The diplobacillus lives only on the human conjunctiva, and its transmission takes place from man to man directly. In an epidemic, two, three, four or even all of the members of a family are affected. The affection attacks most often persons of the poorer classes among whom the observance of the laws of hygiene is not at all strict. The diagnosis of this trouble becomes quite easy with a little practice.—*Revue Médicale de la Suisse Romande*, October 20, 1901.

Arthritism in Children.—J. Comby declares that arthritism is almost always hereditary, and is a permanent trouble of nutrition. In the child it presents only rarely striking manifestations, and it is easy of classification. The young arthritic is an intelligent child, with an alert eye and quick movements. It often shows the characteristics of the lymphatic temperament. Anæmia is sometimes marked. Circulatory troubles are frequent, as are also respiratory affections; epistaxis, and asthma. There are often digestive troubles, such as anorexia. Albuminuria is sometimes found. The skin is fine and easily irritated. Diet plays a most important part in the prophylaxis and treatment of arthritism. Vegetables, water, milk, fresh fish, white meats, and cooked fruits are indicated.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, *September 29*, 1901.

Clinical Notes on Twenty-six Cases of Eclampsia.—Hirigoyen, in his hospital service, has observed twenty-six cases of eclampsia among 2,200 pregnant women. Three women died, but one died from the rupture of the lower segment, so that really only two patients died of eclampsia, pure and simple. The number of children who died was five, while twenty-one survived. Nineteen of the women were primiparæ, seven being multiparæ. Nine times the eclampsia developed after delivery. The quantity of albumin in the urine was not in proportion to the gravity of the eclamptic manifestations. The prognosis was variable. When the trouble developed *post partum*, it was generally less grave; but there were exceptions. The treatment consisted in milk diet at first, injections of serum, intestinal douches, administration of chloral, and bleeding when necessary. Unfortunately, the treatment is often futile. As to the induction of abortion, this is accomplished when the case is grave, but in other cases the termination of labor is merely facilitated.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 27, 1901.

Medicinal Eruptions from an Internal Cause.—Henry Bernard, in describing the characteristics of medicinal eruptions, says that, generally speaking, these eruptions are polymorphous in their manifestations, more or less generalized, and frequently incoördinate in their clinical manifestations. They are often devoid of general phenomena, and they may or may not coexist with other symptoms of medicinal intoxication. They always cease at a longer or shorter period after the administration of the drug which has caused them is stopped. There is scarcely a drug, whatever may be its origin—chemical, vegetable, or animal—which may not, under certain conditions, cause an eruption. This eruption may vary widely in appearance, and its diagnosis is sometimes difficult. The writer enumerates many drugs with their eruptions, among which are the following: Quinine, particularly the sulphate of quinine, produces all sorts of eruptions, the most frequent, however, being a temporary erythema, without pruritus or desquamation. Salicylic acid and the salicylates sometimes cause eruptions which are erythematous, bullous, or purpuric in character. There is nothing characteristic of this drug. Belladonna and digitalis in some cases cause simple erythematous, in other cases scarlatiniform, eruptions. Antipyrin is one of the most common causes of drug eruptions, which appear in various forms.—*Gazette des Hôpitaux Civils et Militaires*, October 26, 1901.

American Journal of the Medical Sciences, *November*, 1901.

Some New Points in Regard to Raynaud's Disease.—Carl Beck reports two cases, and by means of skiagraphs proves that the tissue changes in this disease are not confined to the soft tissues, but that they also affect the bones. There is osseous proliferation at the upper end of some of the phalanges, and thickening of the epiphyseal ends of the metacarpal bones.

Typhoid Cholecystitis, with Observations Upon Gallstone Formation.—Joseph H. Pratt states that bacteria possibly infect the bile in two ways: (1) An ascending infection through the biliary passages from the duodenum; (2) A hæmatogenous infection. In typhoid fever, the infection would seem to take place through the blood. The typhoid bacillus is nearly always found in pure culture in the gall-bladder. Judging from experiments which have been made, the typhoid bacillus induces gallstone-formation. There are two classes of cases of cholecystitis caused by the bacillus typhosus: (1) Cholecystitis secondary to typhoid enteritis; (2) Cholecystitis due to a primary infection of the gall-bladder. The writer notes one case in which the biliary calculi contained living typhoid bacilli three months after their removal from the patient.

Tuberculosis of the Portio Vaginalis and Cervix Uteri.—Henry D. Beyea declares that the subjective symptoms of tuberculosis of the cervix are indefinite and not at all characteristic. As a rule, the symptoms are referable to lesions of the uterus, tubes, or peritoneum. The patients are generally in good physical condition. The most frequent symptom has been a very profuse purulent leucorrhœa, sometimes tinged with blood. In some cases there is menorrhagia, in others amenorrhœa. The two important clinical varieties are tuberculous papillary hyperplastic endocervicitis, and the ulcerative form. The former resembles excessive non-tuberculous papillary erosion of the cervix, and also the rare cases of malignant adenoma of the cervix. The ulcerative form resembles syphilitic chancre. The treatment of tuberculosis of the cervix is, as a rule, operative.

Remarks on the Diagnosis of Some Forms of Ophthalmoplegia.—L. F. Adt believes that the diagnosis of nuclear palsy must by made with reserve in all cases of even partial monocular ophthalmoplegia. The muscles of the motor oculi most apt to be affected in a case of monocular ophthalmoplegia are the internal ocular and the levator palpebræ. In a case of monocular ophthalmoplegia, with a sudden onset affecting any of the muscles which move the eyeball supplied by the third nerve, while others escape, the lesion is in the tegmentum of the crus cerebri. In a case of binocular paralysis of this form, with a sudden onset, the lesion is in the nucleus of the third nerve on the floor of the aqueduct of Sylvius. These rules, to a great extent, also hold in cases with a chronic onset. In cases in which lesions in the base of the brain or in the orbit implicate some of the third nerve fibers, similar forms of paralysis occasionally occur. This is especially true in syphilitic disease of the base of the brain, where only a part of the fibers of one or both motor-oculi muscles are involved by gummatous exudations.

An Epidemic of Noma; Report of Sixteen Cases.—George Blumer and Andrew MacFarlane define noma as a disease characterized by a rapidly developing gangrenous sloughing with frightful destruction of tissue. This affection occurs almost exclusively in children, and generally between the ages of three and eight years. The mucous membrane of the mouth—gum or cheek—is most often attacked. The disease quickly attacks the periosteum. The mortality is very great on account of the exhaustion. It is supposed to occur in children recovering from acute disease, and whose hygienic surroundings are bad. Measles, scarlet fever, and typhoid fever are the most frequent precursors. In these sixteen cases, the mouth only was affected in four cases; the mouth, the ear, and vulva in three cases; the vulva alone in two cases, and with other parts in seven. Among the fatal cases, noma involved the mouth in three children and the rectum in four. The ages of these children ranged between three and twelve years. These sixteen cases would seem to be rightfully called an epidemic. The beginning of the disease was a slight ulceration of the mucous membrane, with an area of extreme hardness surrounding it. There was no complaint of pain. The general treatment was stimulating, consisting in the administration of alcohol, iron, quinine, strychnine, nitroglycerin, and concentrated nourishment. The local treatment consisted of cleanliness, frequent douching with 50-per-cent. boric-acid solution, then with pure hydrogen dioxide, and continual wet dressings of Labarraque's solution. When the destruction was not too great, the use of the Paquelin cautery under chloroform seemed to stop the process. The writers conclude that this affection probably originates as a simple infection, but is later a mixed infection, and is most frequently due to a long threadlike organism of the leptothrix type, which does not grow upon ordinary culture media.

A Consideration of Certain Details in the Management of the Pregnant and Puerperal Patient.—William R. Nicholson thinks that there is need of more careful study of the seemingly normal case. As soon as the diagnosis of pregnancy is made, the urine should be examined, and also the heart and the lungs. General advice should be given regarding diet, exercise, and personal hygiene. The diet should be nourishing and simple. The daily bath may be taken with caution against the cold plunge. The more severe forms of exercise should be avoided. Constipation should be combated by the milder laxatives. Salts and castor oil had better be forbidden. About two months before confinement the size of the pelvic inlet should be estimated. Next, the position of the child should be determined. External version may be necessary. An important preparation for labor is the full tub-bath. A soap-and-water enema should be taken. Ordinary clothing ought to be removed by the middle of the first stage. All interference with the genital tract before labor, by means of douches or frequent examinations, should be strictly avoided. Labor must be conducted under the most careful aseptic precautions. Rubber gloves should be used whenever there is any reason to mistrust the condition of the hands, although they must always be carefully sterilized. In regard to the puerperal woman, all tears—except lacerations of the cervix—should be repaired within twenty-four hours after labor. The average time that the patient should be kept in bed after labor is twelve days. After forty-hour hours, the patient is encouraged to change her position from time to time, even lying at times upon the face and abdomen. The pad should be applied above the fundus uteri, not immediately above the symphysis. At the end of his attendance, the physician should make a thorough examination of his patient to see that all is going well.

Annals of Surgery, October, 1901.

Pneumococcus Arthritis, Primary in the Knee Joint.—D. P. Allen and C. Lull report a case of this rare affection, it being but the fourth on record. The patient was a single woman of forty years, who commenced her illness with abdominal pains, which later left this region and attacked the left knee joint. In the course of four days the joint was aspirated and pus found. It was removed under the strictest antisepsis by opening the joint, but general sepsis supervened, and an amputation was performed at the junction of the middle and lower third of the thigh. Evidences of general sepsis continued, and the patient finally died, after an illness lasting in all seventeen days. Examination of cover-slip preparation taken from the amputation stump showed the presence of pneumococci, together with some staphylococci pyogenes aurei. Cultures from the lungs were negative, and microscopic examination of sections from these organs showed no pneumonia. In the light of the autopsy findings it seems clear that the pneumococci in the amputation wound were present before operation, having spread through the tissues from the infected joint. The staphylococci probably reached the wound secondarily from the skin.

The Worsted Truss in Inguinal Hernia.—J. C. Hubbard says that worsted is preferable for the purpose indicated, as it is cheap, can be washed, worn in the bath, and is less liable to irritate the skin than a spring truss. The same skein can be used a number of times, but is useless after its elasticity is gone. The material is ordinarily sold in a skein made up of two laps. A lap, or half of a skein, is sufficient for a truss, and the other half can be kept in reserve to be used when the first is soiled. The method of application is as follows: The child is placed on his back, the half-skein is passed under him and pulled far enough so that the end just reaches the internal ring. The other end is then passed through the loop of this first end and the hernia is reduced. The bunch of worsted made by the looping of one end through the other is adjusted carefully and firmly over the hernial opening, and the free end then passed under the leg and fastened by a bit of bandage to the part on the back. If the skein is so long that there is a mass of extra worsted in the back where the perineal arm fastens to the horizontal part, a neater and more comfortable truss can be made by rewinding the worsted, making it the proper length. The truss should fit snugly, and should be worn at night as well as during the day. Whenever it is to be changed, the child should lie down. Occasionally the skin of the groin becomes chafed. This can be guarded against and prevented in most of the cases by keeping the parts dry and by changing the worsted as often as it becomes soiled by urine or dejections.

Milton's Method of Exposing the Anterior Mediastinum Modified for Ligature of the Innominate Artery.—B. Farquhar Curtis thus describes the steps of the modified operation: (1) A median incision is made from the larynx to the middle of the sternum or lower, dividing the skin and deep fascia above and the periosteum also below. (2) The sternohyoid and sternothyroid muscles are followed down to their sternal insertion, retractors being placed so as to draw the soft parts at the base of the neck widely apart. (3) A transverse incision is made through the periosteum along the upper border of the manubrium, and the periosteum and muscles detached from the posterior surface of the bone by blunt elevators and the finger as far as can be reached. (4) The ordinary amputation saw is then applied to the bone in the line of the vertical incision in the periosteum, the soft parts in the neck and behind the sternum being protected by flat metal strips. It should cut most deeply above, and entirely divide the manubrium at its upper border, the cut being more shallow below, and only grooving the bone at its lower end. (5) A stout chisel is then applied in the saw-cut at the superior border of the manubrium, and the thin layer of undivided bone on the posterior surface is made to give way as the wedge action of the chisel forces the two halves apart. (6) The skin being well retracted, a transverse incision is made in

the periosteum across the face of the bone at the level of the first or second intercostal space, and the chisel is applied in this line directed obliquely outward from the middle line on each side so as to divide each half of the bone from the body of the sternum. The instrument must not be allowed to cut entirely through the bone at the outer border for fear of injury to the pleura or internal mammary artery. (7) Strong retractors are then inserted in the median saw-cut, and with a little force the two halves can be sufficiently separated to allow access to the periosteum, which should be carefully incised or scratched through with the point of the knife, beginning above where the danger of damage to the subjacent parts is least. As the periosteum is divided, the halves of the bone can be more widely separated, and this interval gradually extends from an inch to nearly twice that distance. (8) The muscles and fasciæ are then divided by blunt dissection, or with forceps and scissors in the median line, beginning above, double ligatures being applied to the veins which cross the line of incision.

Archives of Pediatrics, October, 1901.

An Analysis of Thirty-two Cases of Congenital Heart Disease.—John Lovett Morse presents the following interesting points from his study of these cases: (1) In a considerable proportion of cases the cardiac lesion was discovered during a routine physical examination, there having been no symptoms referable to the heart. (2) The length of time that the condition existed without the development of any symptoms, several children having shown no symptoms at three and four years of age. (3) The comparative mildness of the symptoms in cases of patent foramen ovale. (4) The recovery from lesions, which, upon physical examination, were apparently the same as those in cases which resulted in chronic invalidism or death.

Maternal Impressions, Report of a Case.—B. K. Rachford describes this case. The mother was operated on for appendicitis when she was two months pregnant with the child. A stitch abscess developed, leaving stitch scars. When the child was one year old, there developed stitch scars on her abdomen exactly corresponding to those of the mother and in the same position. These markings were neither scar tissue nor pigmentation, but depressions in the skin. The writer believes that the maternal impressions which produced these markings on the child resulted from the strain on the stitches in the abdominal wound of the mother during the forty-eight hours of vomiting immediately following the operation. The impressions occurred about one week prior to the termination of the third month of [illegible] gestation.

Appendicitis in Children of Two Years and Under.—J. P. Crozer Griffith reports a case of appendicitis, the patient being only three months old. The baby was very ill when admitted to the hospital, and no operative interference was attempted. The child died the next morning. From the evidence furnished by the autopsy the cause of the disease seemed to be a kinking of the appendix, probably due to the short mesentery and to the other unusual and unusually tight bands which kept the lower half of the appendix firmly fixed, while the distal half was free to move. There were no concretions or foreign bodies present in the appendix, and nothing else discoverable to account for the obstruction to the lumen and to the circulation which had evidently existed in the terminal portion of the organ. The chronic lesions indicated that this infant had suffered from a previous attack of appendicitis.

Acute Recurring Respiratory Failure in the Newly Born, with Symptoms Apparently of Bulbar Origin.—Irving M. Snow reports two cases. The first patient was a baby four days old. The baby who before this had been in good condition, now suddenly grew cold and blue, and the breathing became shallow and irregular. For nineteen hours the baby showed the most alarming symptoms as follows: (1) Frequent stoppage of respiration with intense cyanosis and no spontaneous effort at natural breathing. (2) The frequent occurrence of convulsions which seemed closely associated with the respiratory pause. (3) Intense exaggeration of the pharyngeal and anal reflexes. When the intestine was irrigated, or food or medicine was given by rectum or mouth, the child grew rigid and ceased to breathe. Life seemed to be sustained only by artificial respiration and the continuous administration of oxygen. Only whiskey and chloral had been given hypodermically. Later, a soft catheter was pushed into the œsophagus, and by this means two drachms of breast milk were injected into the stomach. This procedure was successful, and the baby made a good recovery. In the second case, the principal symptom was the sudden cessation of breathing every quarter of an hour. This infant continued to grow weaker until it died. No autopsy was allowed.

Tuberculosis of the Female Internal Genital Organs; Secondary Infection of the Peritoneum and Intestine.—J. L. Dueñas reports this case. The patient was a colored girl, aged eleven years, with no syphilitic nor tuberculous taint in the family. The girl was, with slight exceptions, in good health till about seven months before she entered the hospital, at which time she developed measles. At the end of this time a moderate anasarca appeared with scanty urine. These symptoms disappeared spontaneously in two weeks. Fever, diarrhœa, and loss of flesh persisted for four months, followed by a period of apyrexia, which lasted for three months, during which time the abdomen continued to grow in size. There were abdominal pains of no great intensity. The abdomen measured 82 cm. in circumference. There were no signs of anything abnormal in the respiratory, digestive, or cardiac systems. There was considerable ascitic effusion. The abdomen was oval in form. For two months before entrance to the hospital the girl's condition appeared to be good. Her intestinal functions were regular. Two tappings were performed, and later laparotomy was decided upon. Salpingo-ovarian tuberculosis was discovered. From both the macroscopical and microscopical examinations it could be inferred that the oldest lesion in this case belonged to the appendages of the uterus from which the process was secondarily propagated to the peritoneum and the intestinal mass. From the pathogenic point of view it seemed that the genital lesion of the girl was primary. It is difficult to state whether the beginning of the infection took place through the vulva, or whether the bacilli made their way through the blood.

[illegible] Pat[illegible] August 31, 1901.

A Study of the Elaboration of Eberth's Bacilli by the Kidneys During and After Typhoid Fever.—B. N. Kh[illegible] concludes from his investigations in fifty-five cases that, when the urine of typhoid patients contains Eberth's bacilli, they disappear any time from the third to the thirtieth day after the cessation of the fever, only in rare cases lasting for years. The urine of typhoid patients or convalescents should be regarded as a source of infection, and sterilized by one means or another. Internal medication capable of disinfecting the urinary passages should be administered. The urine of convalescents from typhoid should be carefully examined for the bacillus. In [illegible] and obscure cases, the [illegible] of the urine may assist in diagnosis.

Clinical Forms of Mercurial Angina; a Case of Buccal Affection Simulating Relapsing Herpes of the Mouth.—G. E. Glart[illegible] reports the case of a syphilitic patient, who during mercurial treatment and long after, suffered from a throat affection. The lesions, which were [illegible] and superficial, were round or oval plaques, of whitish color and very painful. They would almost entirely disappear to reappear again in from five to [illegible] days, and this went on for about three months. The tongue was also involved. To all appearance, it was a case of relapsing herpes, but was undoubtedly due to the mercurial treatment.

Plasmolysis in Bacteria.—Alexandre Ivanoff in his experimentation has been unable to obtain the process of plasmoptysis recently described by A. Fischer, and observed even plasmolysis only when the bacteria were taken from one salt solution and placed in another, of whatsoever degree of concentration; plasmolysis did not occur when the bacteria were transported directly from the cultures to even a strongly concentrated solution. The author concludes that plasmolysis in bacteria is not a simple physical process depending on osmosis, but a complicated process in which the alimentation of the bacteria and the composition of their protoplasm play the chief part.

The Bacillus of Acute Contagious Conjunctivitis (the Koch-Weeks Bacillus), and Its Relation to the Grippe or Pfeiffer Bacillus.—F. Rymowitch has found that these two varieties of bacilli are morphologically identical. The conditions of their multiplication in a nutritive medium and the appearance of the cultures are precisely the same. Under the same conditions, both bacteria develop alike, and both have equal tendencies to symbiosis with certain microbes. Their action on the human organism is the same; they are toxic without producing a general infection. The author concludes that the bacillus of acute conjunctivitis and that of the grippe are the same, and that in the mucosa of the respiratory passages it produces grippe, while in the conjunctiva it causes acute conjunctivitis, or to express it differently, grippe of the eye.

A CIVILIAN WAR HOSPITAL. [illegible] ANTHONY A. BOWLBY, [illegible] 8vo, 8-327 pp. New Y[illegible] 1901.

This book, based upon th[illegible] hospital attached to the B[illegible] S[illegible] though supported by pr[illegible] by civilians, is clearly writt[illegible] The subject-matter deals with the [illegible] ment of such a hospital of 100 [illegible] also the conclusions reached by the [illegible] to the camp diseases and gunsh[illegible] th[illegible] service in the field brought them [illegible]

Beginning with the chapter [illegible] equipment of the hospital, the reader is [illegible] impressed with the fact that, in the matter of equipment of field hospitals, the Medical Department of the United States Army as at present outfitted for the field has nothing whatever to learn from the British medical service on the lines on which this hospital was organized. The weight of this hospital for 160 patients amounted to no less than seventy tons, where the U. S. Army hospital of 100 beds weighs not more than one-seventh as much, the latter being transported in half a dozen army wagons, while the field hospital in question needed a railroad train of some fourteen cars to move it. If similar conditions prevailed throughout the British army, its inability to leave the railroad, wage an aggressive warfare, or cope with a mobile enemy, is readily explained. The cots used in this hospital weighed sixty pounds each, while those used in our own field hospitals weigh but seventeen pounds each. Glass and china tableware were also carried with this hospital, and there are many other evidences of the retention of heavy, cum-

[illegible]

[illegible] a short discussion [illegible] and [illegible] excellent [illegible] graphs. The [illegible] used as a [illegible] injuries involving [illegible] and th[illegible] enthusiastic as to their value in military surgery. The[illegible] summarily [illegible] the popular charge that the B[illegible] used poisoned bullets, but at the same time show that the latter at times used [illegible] mushrooming bullets, and illustrate the mangling effects produced by the latter. Like nearly all military surgeons with actual experience on the battlefield they are very skeptical as to the hard-and-fast rules of "explosive action" attributed to the full-mantled bullet, within certain ranges, by experimental investigators. On page 177 they say: "It may be said in general terms that the actual experience of gunsh[illegible]

fractures in war does not confirm the [illegible] definite conclusions arrived at as a result of experiment in times of peace, so that, although much has been learned, it was soon evident that there was yet a good deal more to learn on this subject, and that there had been a tendency to be too dogmatic as to the effects of high-velocity projectiles." Again, they say on page 180: "There are many factors to consider in determining the nature of a gunshot fracture, and no mere consideration of the bullet or the range is sufficient for a proper appreciation of the results observed." They place the chief factors in determining the character of gunshot wounds, in order of importance, as follows: (1) Range; (2) Character of bone; (3) Angle at which the bone was struck. As a result of their experience, the authors conclude that bone injuries are liable to present the appearance of "explosive action," at any range, while wounds of tissue not involving bone rarely show any "explosive action," even at the shortest range. "We do not think that the range, or what is the same, the velocity, has any appreciable effect when soft parts alone are involved. . . . When, on the other hand, bone is struck, and a good resistance is offered to the onward passage of the projectile, the velocity becomes an important factor, and the higher the velocity, the greater the damage and splintering done to the bone." (Page 104.)

Wounds with lodged bullets appeared to heal as kindly as if the missile had passed out. The good results obtained with bullet wounds were believed by them to be due (1) To the small wound produced by the Mauser, (2) Favorable climatic conditions and, (3) Early antiseptic dressing. These views differ from those of our own army surgeons, who regard the antiseptic dressing as of by far the greatest importance. With regard to the enlargement of wounds for the removal of bone fragments, the authors believe that the character of the external wound furnishes a safe guide. If the wound opening be large, the bone fragments must be removed, but if the external wound be small, such removal is not usually required. Fragments of bone attached to the shaft should not be removed, as experience shows that these do not ordinarily necrose. The authors never performed or advised amputation for an uncomplicated bullet wound, and state that the assumption of this position never subsequently caused regret. Joint injuries caused no trouble aside from that due to bone comminution, and these injuries were habitually treated like simple flesh wounds. Excision of joints is regarded by them as an operation of the past, and as no longer indicated. There seemed to be no increased danger from hemorrhage in Mauser wounds, and they state that death on the battlefield from hemorrhage from wounds of the limbs rarely occurred in South Africa. Traumatic aneurysm, however, gave rise to much difficulty, and ligation was unexpectedly often followed by gangrene. With regard to wounds of the skull, the authors say on page 220: "It may be stated here that the expected disruption effects of the perfect Mauser bullet have not been seen. . . . In cases of bullet wound of the skull at ranges observed in this war, practical experience has not borne out the deductions of experiment." Wounds of the lung usually made good recoveries, but such cases do not bear rough handling, and transportation without ill effects. Laparotomy has saved but few soldiers, but must be regarded as among the unsuccessful operations in field surgery. The point is emphasized, however, that wounds affecting the peritoneal cavity do not necessarily imply perforation of the intestine, and that a number of cases of supposed injury of the intestines which recover without operation, very probably belong to this class. A number of cases are given to illustrate this point. Wounds of the large intestine are much more liable to recover without operation than are those of the small intestine. While the general opinion of military surgeons in South Africa was to the effect that 20 per cent. of wounds of the intestine recovered without operation, the authors were inclined to regard this estimate as too high, and call attention to the fact that injuries to the intestine should be studied as to their fatality rather on the firing line than in the hospital.

On the whole, there is much to commend in this book, which, though apparently written for the lay as well as the professional reader, and neither suited nor intended to serve as a textbook, nevertheless contains much valuable information, and is well worthy of careful perusal by the military surgeon. The large number of unusually good photographs and radiographs in the book add much to its value and attractiveness.

A Manual of the Practice of Medicine. By George Roe Lockwood, M.D., Professor of Practice in the Woman's Medical College of the New York Infirmary. Second edition, revised and enlarged. Philadelphia and London: W. B. Saunders & Co., 1901.

In his preface to the first edition, the author makes the claim that this work presents the essential facts and principles of the practice of medicine in a concise and available form, adapted to meet the requirements of those who heretofore have been obliged to resort to the larger works of reference. As far as it goes, the work justifies in great measure the author's claim, but it comes short of the ideal in several respects. In the section on yellow fever, for example, no mention is made of the mosquito theory of the propagation of the disease, notwithstanding strong arguments in its support which have been advanced from time to time during more than a year. Then, again, such an important disease as Malta fever is not treated of. Nothing is said of the prevalence of typhus fever on the Mexican plateau, although this is a matter of some moment to American physicians. However, these faults do not detract seriously from the value of the work as a guide to the student or young practitioner.

Lessons on Massage. By Margaret D. Palmer, Masseuse and Manager of the Massage Department of the London Hospital, Instructor of Massage to the Nursing Staff of the London Hospital, etc. New York: William Wood & Co., 1901.

The number of satisfactory works on the subject of massage is not so large that there is no room for one like the present. This volume is written by a woman of experience who has incorporated enough anatomy and physiology in her book to make it a valuable textbook for the student of massage, while at the same time the physician, who does not need instruction in those subjects, will find much of interest between its covers. Emphasis is laid upon the fact, too often not appreciated, that massage is not the unscientific, though well-intentioned, rubbing so often dignified by the name, but that it is a system of manipulation founded on certain principles, which, when carried out properly, will give certain results. An interesting historical chapter precedes those in which the various forms of movements and manipulations are taken up. The latter are elucidated by many well-executed illustrations which add much to the ease with which we are able to understand the subject, and to our ability to see the practical application of what has been said in the text. Much more can be accomplished in medicine and surgery by massage than is generally supposed, though knowledge of this form of therapeusis is becoming more diffused than formerly, and results are becoming increasingly better. A glossary is added to this volume, chiefly of value to those who have not studied medicine.

Medical Directory of New York, New Jersey, and Connecticut, 1901. Published by the New York State Medical Association. Vol. III. 12mo, 940 pages.

The third volume of this useful annual is somewhat enlarged as compared with its predecessors. A desirable departure is made in publishing the names of all licensed practitioners, irrespective of their school of practice. This not only enhances its value as a book of reference, but in a very practical way takes a very effectual stand against all illegal practitioners who are not recognized in the list.

The general arrangement of the volume is the same as previous ones. Altogether the work has made itself indispensable to the busy consultant and practitioner who wish to keep in personal touch with their professional brethren in the city and the adjoining States.

Materia Medica, Pharmacy, Pharmacology, and Therapeutics. By W. Hale White, M.D., F.R.C.P., Physician to, and Lecturer on Medicine at, Guy's Hospital, London. Edited by Reynold W. Wilcox, M.A., M.D., LL.D., Professor of Medicine and Therapeutics at the New York Post-Graduate Medical School, etc. Fifth American edition, thoroughly revised. Philadelphia: P. Blakiston's Son & Co., 1901.

This edition, following soon upon the last, is some forty pages larger than its predecessor, twelve pages of new matter having been added.

The editor's own work is indicated by brackets. The pages bear evidence of condensation and careful revision, and no little attention has been paid to unofficial preparations both from the standpoint of current literature and personal experience in practice. Thus, a work originally so good that it has become a standard in the colleges is kept up to date, and stamped with the necessary modifications to make it of the greatest use to students on this side of the Atlantic.

La Photothérapie. By Dr. H. Lebon. Paris: Société d'éditions scientifiques, 1901.

A brochure of thirty-five pages, giving a glance over the treatment of dermatoses by concentrated chemical rays of light, chiefly dealing with the Finsen method.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 17, 1901.

GEORGE L. PEABODY, M.D., VICE-PRESIDENT, IN THE CHAIR.

A Clinical Discourse on the Gift of Helmholtz to the Medical Profession by the Invention of the Ophthalmoscope Fifty Years Ago.—DR. HERMAN KNAPP delivered this discourse. He said that in 1851 Helmholtz had presented his "eye mirror" to the Medical Society of Königsberg. Most important discoveries had been made with it, and the era of those discoveries was not yet past. He would limit his remarks on the present occasion to a number of conditions in which this instrument had been an aid to the science and art of medicine.

Latitude in the Appearance of the Normal Fundus.—He desired especially to speak of the latitude in the appearance of the normal fundus oculi leading to errors in diagnosis and treatment in functional diseases, such as nervous asthenopia and hysteria. For example, a school child is brought to the oculist with the statement that it cannot see well or read clearly for any length of time. The child reads only 20/50 or 20/70. If such a child were given glasses as strong negative as positive, so that the one glass neutralizes the other, the child would be found to read well. On examining the field of vision some contraction might be found, but it would be difficult to map it out. The mobility of such an eye would be found normal. It was just those children in whom the varied normal ophthalmoscopic picture passed over the pathological border line that much harmful treatment had been resorted to. This concentric limitation of the field with asthenopia, the result of a neurasthenic condition, leads to many errors, especially if the patient happen to be a petted child of wealthy parents. The speaker cited a case of this kind, from his experience, in which a girl had promptly recovered full sight by sending her to the opera, where she had spent hours using the eyes with the keenest attention. Diplopia of one eye, not the result of an optical disturbance such as dislocation of the lens, belongs to the same category.

Choked Disk.—It was well known that choked disk is found in cases of brain tumor, abscess, meningitis, and sinus thrombosis. It is found in meningitis, particularly in children, yet he had known a number of such children to recover. The prognosis hinged upon the preservation of the acuteness and the field of vision. If there were no symptoms of severe cerebral disease, such as constant pain and vomiting, and the acuteness and field of vision were normal, the prognosis, while grave, would be fairly represented by the statement that the chances of living or dying were about equal. Choked disk, in connection with abscesses of the ear, were not uncommon at the present day. Sometimes the ophthalmoscope would decide the diagnosis. The ophthalmoscope would show the presence of optic neuritis, and the history would indicate the probability of infection from the ear, or else the slow growth of an intra-ocular tumor. Sinus thrombosis did not show so much choked disk as congestion of the optic nerve and retina. This sign was present in the majority of cases, and was a useful aid to diagnosis and a distinct indication for operation.

Atrophy of the Optic Disk.—Atrophy of the optic disk might be post-neuritic or tabic. In the former, the disk is white, and there will be probably some tortuousness of the vessels. In tabic atrophy the disk is of an even, pearl-gray color, and without inflammation. According to his experience, tabic atrophy was completely uncontrollable.

Toxic Amblyopias.—The toxic amblyopias were principally due to poisoning with quinine, alcohol, and tobacco. If he remembered correctly, quinine poisoning of this kind had been first described in this country by Voorhees. The center of the visual field, in such a case, would be regained, but the periphery would be permanently cut off. This condition had resulted from variable doses of quinine. Alcohol and tobacco produce a particular kind of optic-nerve atrophy of the so-called macular bundle. The outer-lower quadrant of the optic disk becomes pale, and later the whole outer half. If the excessive use of alcohol and tobacco continued, the atrophy would be total. He did not remember to have seen the sight completely destroyed by these poisons. It was very remarkable that this kind of optic-nerve atrophy befell that part which in quinine amaurosis was preserved. It was the center of the field of vision which was blotted out, called a central scotoma, which was so characteristic of this form of amblyopia. It was usually observed in those persons that begin to smoke before the age of seventeen or eighteen years, and was quite rarely seen in those who do not begin smoking or drinking until after that age. Possibly the explanation of this was to be found in the fact that those who begin these habits very young are more apt later to use alcohol and tobacco to excess. However, in any case, the lesson to be learned was obvious and should be impressed by physicians upon the public at large.

Amaurotic Family Idiocy.—Warren Jay in London described in 1880 a white halo around the yellow spot in certain children having a weak nervous system. This condition had been further investigated by Dr. B. Sachs of this city, who had named it amaurotic family idiocy. The speaker said that it was surprising that all of the children afflicted with this disease that he had seen had been Hebrews. He mentioned this fact in order to learn if this had been the experience of others. The cause of this strange racial influence was unknown to him.

Retrobulbar Neuritis.—This is a peripheric neuritis in the optic nerve itself, behind the eye. It was sometimes the result of infection with la grippe. Sometimes the sight was lost very suddenly and then regained. He had seen a number of these cases in which the symptoms of la grippe had been more or less distinct. The eyes had gradually recovered.

Bright's Retinitis.—Probably the most important ophthalmoscopic picture of all was that known as albuminuric retinitis. Apart from that, all kinds and stages of retinal inflammation could be met in Bright's disease. Sometimes there was nothing more than a mere congestion with slight œdema. Even in such cases one would often find albumin in the urine. He had seen cases of Bright's disease which had presented the picture of neuro-retinitis, and even of choked disk. The next stage of this form of retinitis was characterized by changes in the blood vessels. The veins were dilated, while the arteries showed a diminution of their caliber. This thickening of the walls of the arteries and diminution of their lumen led to venous congestion, thrombosis, and hemorrhage. The hemorrhages were succeeded by the bright white spots so well known to those who used the ophthalmoscope. The stellate appearance at the macula lutea is occasionally seen in cases of tumor of the brain just as distinctly as in Bright's disease. If the general practitioner would learn to use the ophthalmoscope, he would be able to diagnose Bright's disease in the stage of congestion and slight œdema of the optic nerve and retina. In this stage the disease was curable, or at least by proper dietetic and hygienic treatment its development might be long postponed. It was too late to do anything in the way of controlling the disease when the picture of Bright's retinitis was pronounced.

Embolism and Thrombosis.—In cases of embolism, the arteries are thin and the veins large. Around the optic nerve and over a considerable portion of the retina a milky veil is spread. Gradually about two-thirds of the caliber of the arteries are restored. Incurable blindness is the ultimate result. These patients often say that they

have had several attacks of transitory impairment of sight before the onset of total blindness. These early attacks were best explained on the theory that the caliber of the arteries had been affected by an endarteritis. The cases of thrombosis of the retina that he had seen could be grouped under three heads, viz.: (1) Those due to compression; (2) Those brought about by endarteritis; (3) Those resulting from infection. We were taught that blood stagnating in a healthy vein remains fluid, but he had seen with the ophthalmoscope both parietal and obturating thrombi in the retinal veins.

Intraocular Tumors; Glioma and Sarcoma.—Glioma, the speaker said, occurs in early life much more commonly than does sarcoma. Glioma is almost always fatal. To save life, the growth should be removed early.

Glioma, when well developed, could be recognized with the naked eye, by the yellowish-white metallic luster of the pupil to which Beer, about one hundred years ago, gave the still used name of amaurotic cat's eye. In the earlier stages both these fatal pseudoplasms can be diagnosticated only with the ophthalmoscope.

Foreign Bodies.—They are either magnetic or non-magnetic. Of the aid which the ophthalmoscope may furnish in the removal of non-magnetic foreign bodies from within the eye, the speaker reported a remarkable example. A piece of a gun cap from an exploding toy pistol entered into the eye of a boy through the corneal border of the sclerotic without injuring the lens. It was seen with the ophthalmoscope to float in the vitreous. The speaker, aided by Dr. Gruening and two others, placed the anæsthetized little patient sideways on a table so that he could see with a forehead mirror the foreign body by the sunlight coming from the window. He made an incision into the temporal part of the sclerotic, and fished the foreign body out through the scleral opening, even without loss of vitreous, under guidance of the mirror. The eye recovered, with preservation of its sight.

The removal of magnetic foreign bodies now constitutes an important chapter in ophthalmic surgery. When the foreign body is small, it can be led by the magnet around the lens toward the pupil, and through a corneal incision out of the eye with excellent result. For mechanical reasons, this plan cannot be employed if these bodies are large.

The speaker illustrated his discourse by blackboard drawings and ten large colored charts, all from cases of his own observation; for instance, Waren Tay's macula halo, different forms of Bright's retinitis, embolism of the central retinal artery and its branches, thrombosis of the retinal veins from endarteritis, four successive stages of retinal thrombosis from compression of the retinal vessels by orbital cellulitis in facial erysipelas, which was not fatal and therefore showed the total compression of the central retinal arteries; the black, engorged veins and numerous hemorrhages, then in the convalescence; the partial and temporary return of the retinal circulation, a crop of fresh hemorrhages, and the gradual white obliteration of the veins by organization of the thrombi and plastic periphlebitis, furthermore, a beginning glioma nodule with gliomatous infiltration of the adjacent retina in the case of a child, in which the whole course of retinal glioma had been observed, the beginning in the above eye leading in two and a half years to an immense tumor with metastases in the diploe of the cranial bones, whereas the other eye, which was removed, at six months, showed no local relapse.

In conclusion, the speaker asked the indulgence of the academy on account of the imperfections in the delivery of his discourse. The sudden and prolonged absence of Dr. Weir, the President, had thrust the honor and burden on the Vice-President, and he had not been able to find a speaker for the present meeting. Thus, he had to throw himself into the breach. He could not make the time to write out a careful paper, yet he thought the subject—the fiftieth anniversary of the invention of the ophthalmoscope, would be eminently proper to be brought up before our first medical society. It is a broad and deep subject of which only one part could be presented in one evening. The theory of the ophthalmoscope, the other "scopes," to which it gave birth; the improvement of the original instrument, leading to an evolution of the eye-mirror, like that of the steam engine and other fundamental inventions; its scientific value, by engendering so many important discoveries, are well known and universally appreciated. That this era of discoveries was far from being closed was evident from the recent appearance of the magnificent atlases which he had placed on the table for inspection, of which the newest has aroused his attention and admiration in the highest degree, viz., the first part of contributions to the comparative anatomy of the mammalian eye, chiefly based on ophthalmoscopic examination, by G. L. Johnson, M.D., F.R.C.S., London, 1901; twenty-nine brilliantly executed plates with text, published in the Philosophical Transactions of the Royal Society of London. The speaker's aim in this evening's discourse had been to honor Helmholtz by selecting a series of diseases in which his immortal invention had been of particular benefit to mankind through the medical profession.

Dr. Charles Stedman Bull said that within the last eighteen months he had seen six cases of infectious choroiditis, due to la grippe. The picture given by the ophthalmoscope had been almost startling, the entire fundus becoming, sometimes in twenty-four hours, one mass of infiltration, and the sight being destroyed. Of these six patients, four had died. In his student days he had been taught that there was a typical ophthalmoscopic picture associated with Bright's disease—retinitis albuminurica. We now knew that this was not true, and that Bright's retinitis might simulate a great many other conditions. There was no such thing, then, as a typical picture of albuminuric retinitis; hence, when the ophthalmoscopic picture excites our suspicions of Bright's disease, the urine should be promptly examined, **not** only for albumin, but for casts. At one time he had personally followed 100 of these cases, and had found that 70 per cent. of them had died within a year after the retinitis had manifested itself. Of these fatal cases, 62 per cent. had died within six months. The speaker said that he felt that he was now able to distinguish by means of the ophthalmoscope cases of gout and rheumatism in which the constitutional symptoms were in abeyance at the time or but slightly marked.

Dr. Thomas R. Pooley said that he had come to believe that primary atrophy of the optic nerve, with the single exception of atrophy in tabes, is much more rare than was generally supposed. He believed that the cases were almost all the result of an optic neuritis. It was well known that optic neuritis might exist in a high degree without affecting the sight; hence it might occur in any disease which gave rise to severe choked disk. The speaker then referred to a case of amaurotic family idiocy that had come under his notice, and one seen by Dr. J. Herbert Claiborne, as neither of these children were Hebrews. He was sorry that Dr. Knapp had not dwelt upon the assistance rendered by the ophthalmoscope in cases of albuminuric retinitis of pregnancy. The instrument was here an invaluable guide to the physician as to the time at which premature labor must be induced if sight were to be preserved.

Dr. Sara Welt-Kakels presented a case of amaurotic family idiocy. The parents were healthy and there was no consanguinity between them. Both of them were Russian immigrants of Semitic origin. A very few cases had been reported in children of other races. From the history of this family it seemed probable that the first child had been similarly affected, though according to the hospital records, it had died of hydrocephalus. The baby now presented, the fourth child, is a year old, and was born at full term after an easy labor. For the first few months

it had developed normally. When about three months old, the mother had noticed that the baby could not hold up its head. It was taken to the same hospital at which the first child had been treated, and again the diagnosis of hydrocephalus had been made, and an operation suggested, but declined. The mother had then come to the speaker. There was found to be decided muscular weakness in the upper and lower extremities. The child was well nourished, and an examination of the blood had revealed nothing abnormal. There was some slight hypersensitiveness to sound. The eyes exhibited the characteristic changes in the macula lutea, though not so distinct as in some other cases. In nearly all instances more than one child in the same family was affected.

Dr. E. Gruening said that he looked upon Helmholtz as not only the inventor of the ophthalmoscope, but of the otoscope, the laryngoscope, and all the various instruments used for examining the cavities of the body.

Dr. David Webster said that Dr. Knapp had intimated that it was not always easy to draw the line between the normal and the pathological fundus. To emphasize this very practical point, he cited a recent case in which, by a careful consideration of the clinical history alone, he had been able to decide that there was present a congenital defect of the eye.

Dr. B. Sachs said that neurologists occasionally saw cases in which it appeared that primary optic atrophy occurred independently of tabes. If this were true, the question would arise: Is this primary nerve atrophy a part of some of the other degenerations of the nervous system? Regarding amaurotic family idiocy, he would say that a doubt had arisen in his mind as to whether every case presenting the peculiar and supposedly characteristic appearance of the macula lutea should be put down as one of amaurotic family idiocy. He was positive that the case reported by Dr. Claiborne was not one of amaurotic family idiocy. The fact that such a large proportion of these children were Hebrews was entirely unique. He knew of only one or two thoroughly authentic cases of this disease on record in which the subject had been of another race.

Dr. Knapp, in closing the discussion, said that he had never seen an idiopathic atrophy of the optic nerve; there had always been some general disease, for the most part, of a tabic character, if the atrophy was not post-neuritic. As to the futility of treatment in atrophy of the optic nerve, he begged leave to tell his own opinion and that of the late Dr. Alfred Loomis, who had asked him his opinion about the therapeutic value of electricity in tabic and other atrophies. He, the speaker, answered he thought that electricity in these diseases was next to quackery, to which Loomis replied: "That is too far off."

Stated Meeting, November 7, 1901.

Herman Knapp, M.D., Vice-President, in the Chair.

The Causation of Multiple Neuritis.—Dr. M. Allen Starr read a paper on this subject. He took up first the toxic causes from poison outside the body.

Arsenic.—He said that many persons who attempt suicide by taking arsenic suffer subsequently from a toxic neuritis. Cases were on record, and had come under his own observation, in which the neuritis had resulted from the use of toilet powders containing arsenic and from the inhalation of arsenic from wall paper. An epidemic of arsenical neuritis had been observed in England. Inquiry had shown that the arsenic had been introduced into the system in beer. It had gotten into the beer from the glucose used, and the latter had been made from sulphuric acid obtained from arsenical pyrites. Arsenic being commonly found in copper, it was not surprising that workers in copper are apt to become poisoned with arsenic. In factories in which the copper is heated in order to drive off the contaminating arsenic, the fumes are conducted into chimneys 250 feet high, yet the surrounding atmosphere is poisoned [illegible] that the workmen very commonly suffer from general neuritis.

Lead.—Physicians practising in districts where pottery is made should be on their guard for cases of neuritis arising from lead poisoning. Lead is sometimes dissolved out of the glaze of earthenware and may thus poison the food.

Phosphorous.—It was not unlikely that many of the nervous symptoms observed in those working in match factories are the result of poisoning with phosphorus.

Mercury.—Poisoning with mercury was very common when mirrors were manufactured in the old way. In making silk hats, nitrate of mercury is used in England for producing the gloss on these hats, and those engaged in this work are liable to suffer from mercurial neuritis. Dr. Starr said that he had never seen mercurial neuritis arise from the medicinal use of mercury.

Poisoning by Non-Metallic Substances.—The cases of multiple neuritis belonging to this class were much more numerous than those of the first group.

Alcohol.—It was now known that in some persons susceptible to alcohol, red wines, white wines, and even ale and beer may produce alcoholic neuritis. Some persons who indulge freely in alcoholic drinks for years escape neuritis, while others who take very little alcohol develop neuritis. All the work in factories where the fumes of alcohol may be constantly inhaled are liable to the development of neuritis. The speaker said that he had known one case of neuritis occurring in a woman from sipping cologne. Neuritis was more commonly seen among the higher classes, and in those whose nervous organization is more highly developed than in the lower and more phlegmatic class of people.

Coal Gas.—Coal gas, when inhaled, may cause a very severe form of multiple neuritis. It was not generally known, however, that natural gas may produce the same effect. He had been told that neuritis had increased in Pittsburg since natural gas had come into general use there as fuel.

Bisulphide of Carbon.—Multiple neuritis was sometimes observed among those who work in rubber factories, and results from the inhalation of the fumes of bisulphide of carbon.

Coal-Tar Products. It had been stated recently that such coal-tar products as antipyrin, acetanilid, sulphonal, trional and chloretone might give rise to neuritis. He had not seen neuritis from antipyrin, acetanilid, or phenacetin, but had seen a neuritis develop in a person who had taken an overdose of sulphonal. A case had been recently reported in which trional, taken in large doses for a considerable time, had caused multiple neuritis.

Neuritis from Toxæmia.—In this class were included all cases due to the development in the system of some bacterial poison, either of external or internal origin. Neuritis occurred as a sequel of diphtheria, severe pharyngitis, la grippe, typhoid and typhus fevers, scarlet fever, measles, mumps, whooping-cough, smallpox, pneumonia, erysipelas, gonorrhœa, puerperal fever, and septicæmia of any origin. In this class might be included beriberi and leprous neuritis. Since the general use of antitoxin in diphtheria, the number of cases of neuritis following that disease had been decidedly less. Neuritis following la grippe he had found to be very slow in recovering. Many cases of neuritis following typhoid fever he had thought might be the result of the free and long-continued use of alcoholic stimulants. Neuritis following the children's disorders mentioned was very rare in this country. Some of the cases of neuritis, formerly classified as of unknown origin, were now thought to be infectious in their nature. Beriberi is a form of neuritis, and is likely to be seen in this country among those coming from the Philippines. Many believe it to be due to a diet in which [illegible] im-

inates, but others are of the opinion that it is of infectious origin.

Neuritis and Dyscrasias.—A class of cases of neuritis exists due to some other disease in the body, such as tuberculosis, rheumatism, diabetes, gout, carcinoma, and arteriosclerosis. In diabetic patients local neuritis was of common occurrence, but general multiple neuritis was seldom seen. In gouty patients, also, mononeuritis was far more common than multiple neuritis. In carcinomatous individuals, as in tuberculous persons, the occurrence of neuritis was to be attributed to the general malnutrition. The question of the existence of a syphilitic multiple neuritis had been raised, but it was probable that syphilis is not a factor generally in the causation of multiple neuritis, though it may be of localized neuritis.

Idiopathic Multiple Neuritis.—It could not be denied that there were still some cases of multiple neuritis that could not be classified etiologically under the headings already given, but the number of such cases diminishes as our knowledge increases. Only a few cases of recurring neuritis were on record. One should not be satisfied that the exact etiology of any case had been made out until all possible causes had been eliminated, and in this connection it should be borne in mind that it was not uncommon for two or more causes to coexist.

Clinical Types.—Dr. C. L. Dana said that of late years he had met with very different types of neuritis from those he had seen frequently in former years. He would divide the neuritis into three classes, viz.: (1) Those due to toxic causes; (2) Those due to dyscrasias, and (3) Those due to infections. Nearly all the toxic cases were forms of neuritis in which the whole nerve was involved, and there were both motor and sensory symptoms. Cases of neuritis due to infections, especially to diphtheria, were largely of the motor type. Those forms of neuritis due to dyscrasic conditions, such as rheumatism, gout, and diabetes, were largely of the sensory type—a form that he thought had not been sufficiently dwelt upon by writers on neuritis. This was the type that he had found quite frequently in diabetes. He had noted that many of his patients having neuritis were of a neuropathic nature, or gave a family history of tuberculosis or of some psychosis. He was sure that in some cases the excessive use of tobacco, coupled with a very moderate use of alcohol, caused neuritis. In hospitals, the women were specially liable to neuritis, and all of these women had been found to be excessive drinkers of tea. The use of morphine, cocaine, or any narcotic drug predisposes to neuritis. Alcohol was the most important single factor in the causation of neuritis; according to his statistics, about two-thirds of all the cases of multiple neuritis had this causation. He had seen some cases of multiple neuritis that seemed to be associated with lithæmia, but he did not believe there was any such thing as a rheumatic multiple neuritis, and it was only very exceptionally that gout caused multiple neuritis. He believed that many of the cases of multiple neuritis following infections were really due to something that had been given during the course of the infection; hence, he was disposed to look with suspicion upon alleged new causal factors. The speaker closed by citing a case in which a person had, without his knowledge, taken ten grains of chloretone three times a day for a period of about four months. The man had then developed numbness and anæsthesia of the feet, with more or less ataxia, and sensory and motor symptoms of a beginning neuritis.

Dr. B. Sachs said that a number of years ago, when unusually large doses of arsenic had been given in chorea, symptoms of arsenical neuritis had not been very uncommon. He had seen some cases of multiple neuritis occurring in persons addicted to the use of snuff, and he had attributed the neuritis to poisoning from lead introduced into the snuff to give it an intense black color. He thought there was an unfortunate tendency to make the diagnosis of alcoholic multiple neuritis on insufficient grounds. Such a diagnosis should not be made unless there were other symptoms of chronic alcoholism. He had seen malarial multiple neuritis occurring in children living in the swampy malarial districts of Long Island. In these cases the malarial plasmodium had been found in the blood, and there had been present the usual symptoms of malarial poisoning. He had seen one case which he had been compelled to look upon as syphilitic multiple neuritis. It had occurred in a person who had not received mercurials to any extent, and the use of mercury and the iodide had brought about rapid improvement. This was the only case of the kind, however, that he had seen, and he had made the diagnosis by exclusion. He had also seen diabetic multiple neuritis rather more frequently than Dr. Starr. Certain cases of neuritis he believed were entirely secondary to disturbances of the circulation. The lithæmic cases were purely sensory in character, and were exceedingly obstinate under treatment.

Dr. Frederic Peterson said that it must be evident from the paper that, with arsenic lurking in beer and in our cooking utensils and in our sleeping potions, the danger of living grows greater every day. The facts brought out this evening should constitute a good argument for the establishment of a State Hygienic Institute. The speaker, continuing, said that in alcoholic multiple neuritis there was often a peculiar mental condition characterized by a loss of the sense of time and place. Some years ago he had reported three cases of acute mania occurring in rubber workers from poisoning with the bisulphide of carbon.

Chloretone.—Referring to chloretone, he said he thought very little was as yet known about this agent. He had used it in a number of cases of epilepsy in small doses—three to five grains—and had observed some peculiar effects in some cases. Chloretone was known to be a very uncertain drug in the tablet form. This had been well shown by the case of a young girl who had swallowed 25 five-grain tablets of chloretone without any appreciable effect. He had seen two cases of arsenical multiple neuritis develop from the use of only eight or ten drops of Fowler's solution of arsenic three times a day.

No Diseases Caused by Tobacco.—Dr. Joseph Collins said that he, too, had learned to look upon diabetic multiple neuritis as comparatively common. He would consider a multiple neuritis to be tuberculous when the poison generated by the tubercle bacillus gives rise to the neuritis by circulating through the system. He had just seen such a case. He had met with several cases of tuberculous neuritis, in which the autopsy had shown no characteristic lesion. The speaker said that after long search and expensive experience he had failed to find any disease produced by tobacco, with the possible exception of arteriosclerosis.

Neuritis in Snuff-Takers.—Dr. Collins said that he had seen at least three snuff-takers who had multiple neuritis; and as they had all come from the same locality, he had made an investigation and had found that they had all procured their snuff from one shop, and that the snuff had been packed in lead.

Dr. B. Lapowski cautioned against the free use of mercury in a case of neuritis developing in a syphilitic, unless the examination of the urine seemed to warrant the pushing of this drug.

Neuritis from Coal Gas.—Dr. Herman Knapp reported a case of poisoning by coal gas in which there had been paralysis of several of the eye muscles. It had been necessary to operate upon the muscles in order to prevent double vision. Recovery had been very slow, and after two years he had been directed to go to the mountains, and his sojourn there had apparently done him more

good than all elaborate treatment that had been previously employed.

Neuritis an Improper Term.—Dr. KNAPP questioned the accuracy of the term "neuritis" as employed in this discussion. He said there was no histological foundation for the belief that it is a neuritis, for the ophthalmoscope enabled one to see exactly what occurred. Tobacco amaurosis was characterized by atrophy, not preceded by congestion or any evidence of inflammation: it was an atrophy just as is seen in tabes. He had not been able to convince himself that gout exerts any influence upon diseases of the eye. After an attack of la grippe there was certainly developed a distinct optic neuritis.

Tea-Taster's Disease.—Dr. STARR closed the discussion. He said that it was common in his experience to meet with sciatica and other forms of mononeuritis in diabetes, but he had not seen general multiple neuritis in connection with this disease, and the literature showed that these cases were comparatively rare. He had had one interesting case in an American who had been engaged in Japan for nine years as a tea-taster. This man had had the "tea-taster's disease," but after careful examination he had not been convinced that the case was one of true multiple neuritis, and hence he had not included these cases in his paper. This man had presented symptoms of extreme neurasthenia, associated with very rapid heart action, fibrillary muscular twitchings, and paræsthesia. However, it was probable that excessive tea-drinking by impairing nutrition might lead to a multiple neuritis. He could not agree with Dr. Sachs that the vasomotor type of multiple neuritis is merely secondary to disease of the blood vessels.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, October 24, 1901.

A. BROTHERS, M.D., CHAIRMAN.

Acute Perforative Appendicitis.—Dr. S. MARX presented several specimens. The first was a specimen of acute perforative appendicitis. There was a history of two prior attacks of appendicitis. The onset had been sudden, and when first seen by him the patient had presented the usual evidences of acute general peritonitis. Laparotomy had confirmed this diagnosis, and had failed to show any other cause for the peritonitis than the appendicitis. Apparently, the peritonitis had resulted from a microscopic rupture of the appendix.

Fatal Case of Extrauterine Pregnancy.—The woman had had one child seven years before. Having gone two days over her period, she inserted a catheter into the uterus and left it in for two days. Her physician had then been summoned and had curetted her. She had improved rapidly after this, but four weeks later had very suddenly passed into collapse. The patient had rallied well after operation, but had died twenty-four hours later. From the way she had reacted after the operation, he had almost come to the conclusion that it was wise in these cases to operate promptly in spite of the presence of severe collapse.

Sloughing Fibroid After Labor.—In this case a large mass had appeared at the vulva just about the time the patient had gotten out of bed. There was a foul discharge present. A physician had spent three hours trying to remove this mass, which he had taken to be a placenta. Dr. Marx had operated and removed the mass, partly by morcellation. Her condition growing worse, the abdomen was opened, and then it was found that there was a total gangrene, not only of the uterus, but of the bladder. The woman died of exhaustion thirty-six hours later.

Spontaneous Rupture of the Uterus.—According to the literature, spontaneous rupture is not extremely rare in the presence of placenta prævia. This patient died within a few hours. The autopsy showed the broad ligament to be emphysematous. A laceration extended through the cervix for five inches and a half, and the uterine vessels were completely torn across. The predisposing cause in this case had been the deep tear of the cervix, and the exciting cause the placenta prævia. The cervix had only dilated on one side, and in that direction only at the expense of the uterus.

Porro-Cæsarian Section for Double Uterus.—Dr. L. J. LADINSKI reported this case. For some weeks the woman had suffered from crampy pains, and these had been very severe in the few days preceding the time of the first examination. When first seen, there had been a large ovoid tumor filling the left side of the abdomen, and neither heart sounds nor fœtal movements could be made out. In the left cul-de-sac was a small indefinite mass that appeared to be separated from the cervix by a septum. A diagnosis of abdominal pregnancy or pregnancy in an anomalous uterus had been made. The same evening he had opened the abdominal cavity. The gestation was in the left sac, and the left tube and ovary were intact. On the right side was the other uterus somewhat enlarged. Between the two uteri and to the left of the median line was a short, broad, recto-vesical ligament joining the rectum and bladder for a distance of one inch and a half above the junction. As the fœtus was no longer viable, he had proceeded to remove the pregnant uterus. There was reason to believe that the full-term pregnancy had occurred in one uterus, and the three abortions in the other uterus. The recto-vesical septum was certainly very unusual in double uterus.

Intraperitoneal Rupture of an Ovarian Cyst.—Dr. LADINSKI presented several specimens. The first one was an intraperitoneal ovarian cyst that had ruptured. The rupture was very minute. The patient had been married seven years ago, and had had three children. For about nine months she had noticed a gradual but painless enlargement of the abdomen. She had suddenly gone into collapse, and her physician had found a change in the contour of the abdomen. In addition, the pain had ceased, and the abdomen was filled with fluid. Dr. Ladinski had operated upon her the same day. On opening the abdominal cavity under ether, the peritoneal cavity had been found filled with a dark grumous material, together with the collapsed cyst. This had been removed, and she had made a good recovery, leaving the hospital in two weeks.

Elephantiasis of the Labia Majora.—This woman had been admitted to the Gouverneur Hospital while in labor with her first child. On examination he had found a tumor of the labia, and had recognized her as a woman who had been at his clinic under treatment for a severe syphilitic ulceration of this region. During delivery she had sustained a severe rupture of the perineum.

Carcinoma of the Urethra in the Female.—Dr. A. BROTHERS presented this specimen. The only symptom was difficulty in micturition. He had made an opening into the bladder, and with the finger therein had dissected out widely the entire urethra, and the carcinomatous mass had thus been removed intact. The parts were then sutured as carefully as possible. The condition appeared to be a very rare one, and the literature was scanty. One German writer had collected twenty-seven cases and had classified them as follows: (1) Those presenting warty papillomatous excrescences; (2) Cases characterized by thick, nodular, infiltrating masses in the periurethral tissues; (3) Those with ulcerating surfaces and thickened edges. In one-third of the cases inguinal enlargement was present.

Dr. ROBERT A. MURRAY reported that he had examined Dr. Ladinski's patient with double uterus, and had found the two cervices and a partial septum.

Etiology, Histology, and Usual Course of Ectopic Gestation.—S. W. BANDLER was the author of this paper. He said that external migration of the ovum was believed by some authorities to be the etiological factor. Specimens

were presented to substantiate this theory of external migration. Certain experiments seemed to indicate that in a perfectly normal tube development of the ovum could not take place. Ectopic gestation occurred most frequently in multipara after a period of sterility. The latter marked the time during which the tube had been the seat of inflammatory changes. Recurrences of tubal gestation takes place, but rarely in the same tube. The location of the gestation was generally in the middle of the tube. The ovum might grow in three different ways. (1) The columnar growth. (2) The intercolumnar growth; (3) The centrifugal form. Under normal conditions the villi do not project into the arterial openings of the intervillous space. It was very probable that the villi actually invade the muscle wall. In the intercolumnar type of development the ovum is surrounded by mucosa folds alone. Such a columnar situation made abortion easy and but slightly dangerous. The theory that the tube ruptures, because the ovum is too large, was not usually borne out by the facts in the case of gestations in the first three months, the real cause here was hemorrhage. Rupture of the tube almost always occurs at the placental site, at which point both old and new hemorrhages could usually be found. The majority of tubal abortions were near the uterine end. There might be an intraligamentous tear with a hematocele at the abdominal end. If the bleeding were very slow a secondary hematocele would form.

Early Symptoms of Ectopic Gestation. Dr. Egbert H. Grandin opened the discussion on the general subject of ectopic gestation. He said that from an experience with over fifty cases of ectopic gestation he was satisfied that it rarely runs the course described in the textbooks. Very seldom, indeed, was there a history of amenorrhœa followed by irregular hemorrhages, and very often there was an absence of the colicky pains considered to be so characteristic of this condition. Only once in his series had a decidua been present. There was only one safe course to follow, *i. e.* considering that every woman has an extrauterine pregnancy until it has been disproved. The diagnosis must be largely made by excluding uterine pregnancy. There was usually a history of absolute or relative sterility, and this was an important factor in reaching a diagnosis. Close inquiry would show that the woman had not menstruated according to her accustomed rule; she might have either anticipated the usual date or gone a little over that time. Some of the women give no history of this kind, but insist that they *think* they are pregnant. The gravid uterus is globular in shape and compressible and the lower segment is boggy and projects more or less over the cervix—the so-called Hegar's sign. This last sign was not present in ectopic gestation, except in those very rare cases in which ectopic and uterine gestation coexist. In any doubtful cases a positive diagnosis could be made by an incision into the posterior vaginal fornix—an operation which might fairly be said to be free from risk. As to the question of operating during shock, he would say that while the woman is in collapse the bleeding ceases, as soon as she is stimulated, the hemorrhage recommences. For this reason his rule had been to open the abdomen in spite of existing shock, feeling that, although this added shock to shock, it was following the old surgical rule of cutting down upon the bleeding point and securing it. He had formerly spent a good deal of time in washing out the cavity, but had come to the conclusion that so much handling of the bowel was undesirable. He did not at the present time resort so much to drainage as formerly, not draining at all in the recent cases. In old cases he was still disposed to open into the vagina and carry gauze through, but he was beginning to doubt even the wisdom of this, because of the well-known fact that in about forty-eight hours a drainage channel through the vagina is shut off from the general abdominal cavity.

Dr. S. Marx said that in the majority of his cases there had been a history of antecedent pelvic trouble. He felt sure that the diagnosis of extrauterine pregnancy would be made more often if the physician only thought of this condition. When called to a pregnant woman having hemorrhage he invariably thought of two conditions—placenta prævia and ectopic gestation. Hemorrhage was a most important symptom as was also the small size of the uterus, as compared with the supposed period of gestation. He could not accept Dr. Grandin's description of Hegar's sign. What Dr. Grandin had alluded to in his remarks was not that sign, but one which Dr. Grandin had himself described, *i. e.* the bulging of the uterus above the cervix. Hegar's sign, on the contrary, was the extreme thinness at the vaginal junction. He was not sure whether he would operate during shock or not, because of the risk of being severely censured by the family for operating upon an apparently moribund woman in the event of the case terminating fatally.

Dr. Ladinski said that before one could expect to attain much success in the diagnosis of extrauterine pregnancy, one should have become expert in the diagnosis of intrauterine pregnancy. Statistics show that Hegar's sign is only found in about 17 per cent. of cases of intrauterine pregnancy. There was another sign of early intrauterine pregnancy which was of great value, *i. e.* a peculiar elastic feel in the body of the uterine just above its junction with the cervix. This sign could be detected as early as the fifth week of intrauterine pregnancy. In every case of extrauterine pregnancy there is amenorrhœa, together with tenderness and paroxysmal pain. He saw no necessity for making an exploratory incision, for in cases in which the diagnosis is so much in doubt, operation would be demanded even though the case did not prove to be one of ectopic gestation. He did not favor operation through the vagina. He had seen more than fifty cases of ectopic gestation, and had operated upon thirty-five of them himself, but only once by the vaginal route. He had had 100 per cent. of recoveries. He did not drain or wash out the abdominal cavity farther than to remove the clots. He agreed most heartily that the surgeon was not justified in postponing operation while the patient was in shock, for, while waiting for the patient to react to the stimulants, the woman could be operated upon and saved. Such advice might not have been good before saline infusion was known, but by infusing both before and after the operation one could operate, stop the hemorrhage, and save much valuable time.

Dr. Bandler, in closing, said that the differential diagnosis could not be made between intraperitoneal rupture and tubal abortion. The route to be selected was entirely a matter of individual judgment and choice.

The Plague has reappeared at Glasgow, and several cases have also occurred at Liverpool. In the latter place, suspicion was aroused by two deaths from some undefined disease, and investigation showed that there had been six deaths in the past six weeks of persons whose symptoms suggested plague. There are several suspected cases in hospital. In Glasgow, four of the servants in one hotel were taken ill with symptoms of plague and died. The patients were removed to hospital and the hotel was closed. A number of places have declared quarantine against Liverpool, among which are Havre, Bordeaux, and all the Italian ports. The Texas State Health Department has issued orders to enforce quarantine against all vessels from Liverpool and Glasgow on account of the prevalence of bubonic plague at those ports. At Brisbane, Australia, one death occurred on October 10, this being the first reported case in that city in two months. The disease also exists at Port Elizabeth, South Africa, where five cases were discovered on November 11; at Batum, Russia, and at Rio de Janeiro.

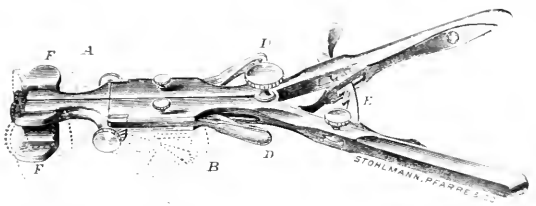
New Instruments.

AN ADJUSTABLE AUTOMATIC MOUTH GAG

By H. W. CARTER, M.D.

NEW YORK.

EVERY anæsthetist is occasionally confronted with the necessity of keeping his patient's mouth open during anæsthesia in order to overcome some mechanical obstruction to respiration, such as persistent dropping backward of the tongue or relaxation of the buccal muscles from atrophy of the alveolar structures, the redundant cheeks acting as valves which permit free expiration, but effectually prevent the entrance of



air during inspiration. This in itself is, of course, a very simple matter, but the application of the modern face piece, when the ordinary gag with its long curved jaws is in use, is almost impossible. Any one who has had a single experience of this kind, and has realized the extreme difficulty of keeping an alcoholic or robust muscular man under ether with his mouth open and the face piece only half applied, will appreciate the necessity of some reliable and efficient remedy in dealing with such an emergency.

The interdental mouth prop is not satisfactory on account of the great danger of its slipping into the larynx and causing strangulation. Having encountered several such cases, I determined to devise an instrument that would fulfil all the requirements of a general mouth gag and at the same time would not interfere with the successful administration of nitrous oxide and other anæsthetics.

To accomplish this purpose and to secure perfect coaptation of the face piece, it was evident that the gag while in use must lie flat against the cheek. A fixed instrument of any kind, for obvious reasons, would not answer, and it became necessary to devise one which could be adjusted to the individual face. This was done by using a hinge joint which permits any degree of motion between extreme extension and full flexion. But while the joint was indispensable for adjustment, it was also absolutely necessary to have a perfectly rigid instrument when in use, on account of the tendency of the hinge to close up and throw the gag out of the mouth. In order to overcome this difficulty, I had made upon the outer surface of either joint a series of nine small cogs into which a peg on the end of a spring lever would successively fit.

This lever operates within a deep slot on the outer surface of either side of the gag, thus reinforcing and making it perfectly secure. When the handles of the levers are depressed with the thumb and index finger, the corresponding joint is freed for adjustment, but as soon as they are released the spring drives the peg into one of the small cogs on its outer surface, making it perfectly rigid. The character of the joint makes it impossible to pinch the lips in any position in which the gag may be used.

I found it necessary to have the tooth rests made automatic so that they would adapt themselves to any position in which the gag might be fixed and would always rest perfectly flat upon the teeth. This feature did away with the necessity of curved jaws and enabled the instrument to be introduced well back into the mouth. As each side of the gag is independent of the other in its mechanism, it is very easy to adjust the jaws to any irregularities or malformation of the mouth. I have adopted the ratchet and spring attachment for opening and closing the gag, because it seems to be the simplest and most convenient one to use. The instrument presented this evening is in no sense intended as a mouth-opener, but as a general gag, pure and simple.

It should prove of great value to the dentist and to the nose and throat specialist in extracting teeth and in removing tonsils and adenoids under nitrous-oxide anæsthesia. Used for this purpose, it should be simply introduced and when the patient is under the anæsthetic, just before removing the inhaler, the mouth should be opened by pressing together the handles of the gag. The instrument is simple in construction and every part of it can be easily taken apart and thoroughly cleaned.

The accompanying wood cut fully shows its different positions and uses.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 9, 1901:

	Cases.	Deaths
Measles	172	3
Diphtheria and croup	257	44
Scarlet fever	141	8
Smallpox	10	1
Chickenpox	25	..
Tuberculosis	264	141
Typhoid fever	65	26
Cerebrospinal meningitis	..	..

Smallpox and the Seasons.—The occurrence of an outbreak of smallpox at the present time of year, which is out of the common course, is a matter of some interest, both in regard to immediate prospects and to the outlook for the future. The seasonal curve of smallpox mortality is a simple one, that is to say, it has one rise and one fall per annum. Taking the mean of a large number of years, the maximum mortality occurs between January and May, when it rapidly falls, the minimum being reached in September. From this point it gradually rises again through October and November, and runs up quickly in December to its maximum in January and February. The fact then, that the present outbreak began at the bottom of the curve, that is, at the time when, under normal conditions, the tendency to smallpox is slight, may by some be taken to indicate that it will be easily dealt with. We do not, however, think that such a view is tenable, in the light of past experience. When we find an infectious disease gradually dying away at a certain season, year after year, notwithstanding that during the preceding months of its maximum prevalence the dissemination of its infection must have been at the highest, it is clear that there must be at work some influence, we know not what, but something connected with the season to account for the phenomenon, and we cannot but believe that an infection accidentally imported during that

* Presented to the Section on Surgery of the New York Academy of Medicine, October 24, 1901.

period of decreasing prevalence is comparatively unlikely to extend. When, however we find that at a given season, as also happens every year, the disease begins to spread, notwithstanding that the foci of infection must be at the minimum, we have to admit that there is some hidden influence at work to cause this result, and again in our ignorance of its exact nature we have to describe this as "seasonal," a something which makes up at such season of the year more potent for evil than at other times. Now, let us apply all this to smallpox. The present outbreak has occurred at the very bottom of the curve, when, under ordinary circumstances smallpox is at the minimum. So far so good. Evidently the season favors our efforts to suppress it, and for the present we may succeed. But the infection which is now being spread abroad by these cases comes into operation at the very season of the year at which, as the natural history of the disease shows, a very little infection always goes a long way. Hence we must not be misled by the fact that this outbreak has so far shown no marked tendency to become epidemic. What we have to think of is what will happen in the early spring. We know that the seed has been sown, and not until harvest time arrives can we be sure that it has not taken root.—*Hospital.*

Disposal of the Milk of Tuberculous Cows.—Professor Sheridan Delépine says: "While I consider it advisable to deal with young stock under three years of age as rapidly as possible, I think that in the present state of things the indiscriminate slaughter of all tuberculous animals above that age would be attended with considerable and unnecessary losses. Only cows in an advanced stage of tuberculosis, showing evidences of wasting, or of tuberculosis of the udder, should be slaughtered without delay. They are serious sources of infection, and the longer they are kept the less their value becomes, if they retain any at all.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 9, 1901:

SMALLPOX—UNITED STATES.

		CASES	DEATHS
Illinois, Peoria	Oct. 1st to 31st	0	
Springfield	Oct. 2d to Nov. 2d	26	
Iowa, Ottumwa	Sept. 28th to Nov. 2d	41	
Kansas, Wichita	Oct. 19th to 26th	3

IS RABIES A SPECIFIC DISEASE?

BY D. E. SALMON, D.V.M.,

CHIEF OF THE BUREAU OF ANIMAL INDUSTRY, UNITED STATES DEPARTMENT OF AGRICULTURE,

WASHINGTON, D. C.

THE article on "Hydrophobia and the Pasteur Methods," by Charles Winslow Dulles, M.D., which appeared in the MEDICAL RECORD, July 13, 1901, reads like a chapter from the medical literature of a dozen years ago. Even at that time such views were comparatively rare, but to-day they are a curiosity. There is but one reason for noticing such a series of misleading assertions, and that is their influence upon the lay press, and the use which is made of them to oppose and obstruct sanitary officers who are endeavoring to protect our people from this dreadful disease.

When John P. Haines[1] some years ago wrote the article on "Rabies and Hydrophobia," which has been scattered broadcast over the country, and which is generally quoted to prove that it is unnecessary to enforce regulations against the disease in animals, he referred to "Dr. Charles W. Dulles, the "Eminent Lecturer on the History of Medicine at the University of Pennsylvania," as one of his principal authorities. After announcing the preposterous claim made for Dr. Dulles that he has "performed the almost incredible task of investigating, either personally or by correspondence, with the physicians or others in attendance, every case of hydrophobia reported in the newspapers of the United States for the past sixteen years," he says: "The result of all this patient and conscientious work has not only brought Dr. Dulles to the conclusion that 'hydrophobia is extremely rare,' but has also inclined him to believe that 'there is no such specific malady,' since he has failed, 'after sixteen years of investigation, to find a case on record that can be conclusively proved to have resulted from the bite of a dog or any other cause.'" Mr. Haines adds: "We need hardly observe that this fact—for a fact it is—reduces the probability that any supposed case of hydrophobia has been really caused by the bite of a dog almost to zero."

Here we have in a nutshell the case of those who oppose the results of modern science and the methods of modern sanitarians. It is distributed from the Atlantic to the Pacific as the mature conclusion of a man particularly eminent in the medical profession, who has devoted many years to indefatigable investigation.

The writer has not investigated all the cases reported in sixteen years, but he has investigated long enough to prove that a sufficient number of cases can be demonstrated in one year to satisfy any unprejudiced man of the existence of the disease, and that it results from the bite of a dog. If Dr. Dulles really wanted to know something about rabies, it is surprising that, instead of attempting to investigate it in the newspapers, he did not confine his attention to his own city of Philadelphia, and use, experimentally, the material which comes to the veterinary department of the university with which he is connected. The dean of that department estimates, that, during the fourteen years' existence of the school, from three hundred to four hundred unquestioned cases of rabies have been received at the hospital. He also knows of several cases of rabies in man that have occurred in Pennsylvania, some of which have been confirmed by the inoculation of animals.[2]

During the two years that rabies has existed among the dogs of the District of Columbia, Dr. Dulles has been frequently quoted by our local newspapers to prove that there is no such disease, and that, consequently, there is no need of sanitary measures to prevent it. The position which he holds in connection with a great university gives his views weight with the public, notwithstanding that he is out of harmony with the great body of his profession, and out of harmony with the results of modern research.

The greater part of the article of July 13 is made up of denunciations of Pasteur and of the Pasteur treatment. It is only necessary to say in reply to these that the views of Pasteur, after the most searching investigation by scientific men, have prevailed; the results of his investigations stand confirmed; institutions for giving the Pasteur treatment have multiplied, and now exist in most parts of the civilized world; and whether these institutions are conducted by private enterprise or as parts of a government service, the reports have been substantially the same.

The views which are most surprising as coming from a physician are (1) That hydrophobia is not a specific disease, and (2) That it is about as likely to follow the bite of a healthy dog as of a diseased one. In view of the fact that rabies may be easily communicated by inoculation from animal to animal through an indefinite series, and from man to animal with equal facility; and further, that such inoculations have been for years and are constantly being made by competent investigators, it is difficult to see how the specific nature of the malady can be successfully questioned. We have as clear evidence of the specific nature of rabies as of any other disease, and we can confirm this evidence at any time by inoculation experiments. Why, then, should there be any doubt?

The conclusion that rabies is about as likely to follow the bite of a healthy as of a diseased dog is absurd on the face of it. What would be thought of a physician who claimed that smallpox, measles, scarlatina, or diphtheria were about as likely to follow exposure to a healthy as to a diseased person? And yet the cases are strictly parallel. An animal is not able any more than is a man to communicate a contagion which it does not possess.

The fallacy of Dr. Dulles's conclusion may be clearly shown, however, by the experience of England during recent years. And in referring to this, I shall take the opportunity to correct a most glar-

ing misstatement which he has made with great positiveness. He says:

"This great disparity between France and other countries has not altogether escaped the attention of the followers of Pasteur, who, in France, have added to their other evidences of ignorance of what goes on outside of their own country by claiming that the comparative immunity of England, Belgium, Holland, Austria, and Germany is due to the administration of effective muzzling laws.

"As a matter of fact, the muzzling laws of England are as inefficient as they are in this country."

In this country we have no efficient muzzling laws. Muzzling is only attempted by city boards of health, consequently does not extend beyond the city's jurisdiction, and in no case which has come to my attention has it been thorough or efficient within these limits. During the last two years it has been attempted by Washington, Buffalo, and Rochester; but in each case met with such opposition that its efficiency could not be compared with the muzzling in England. In Washington it was a farce from beginning to end.

In England, on the contrary, the muzzling regulations are enforced by a central authority—the Board of Agriculture; they are applied wherever the disease appears, and in recent years they have been rigidly maintained. The result has been remarkable, so rapid and complete has been the eradication of the contagion.

The law of 1886 first included dogs among the animals dealt with by the Contagious Diseases (Animals) Act of 1878. The official information as to rabies in Great Britain, therefore, begins in 1887, during which year 217 cases in dogs were reported. At that time it was decided by the Privy Council to give to the local authorities of counties and boroughs the power to make muzzling regulations applicable to the whole or parts of their districts, and to deal with cases of rabies as they might arise. Owing to the want of rigorous and concerted action on the part of the local authorities, little benefit resulted. The number of cases dropped to 160 in 1888, and increased to 312 in 1889.[3]

Early in the year 1889, the disease commenced to spread within the metropolis and the surrounding counties, and became so prevalent in July that it became necessary for the Privy Council to pass a special order requiring the muzzling of all dogs in public places, exempting only dogs used for sport or the destruction of vermin. The order also provided for the seizure of all dogs affected with, or suspected of, rabies, and of all ownerless dogs.

Owing to the long period of incubation of rabies, no material decrease was observable during the first three months, but in November and December there was a marked reduction. The following table shows that within three years after the enforcement of the order, which was issued in July, 1889, rabies was practically extinguished in the district to which the order applied:[4]

1889	176 cases.
1890	44 "
1891	28 "
1892	3 "

At the close of the year 1889, the measures taken by the Privy Council to check the progress of rabies in London had already done such good service that it was determined by the Board of Agriculture, to whom the powers of the Privy Council in this matter had been transferred in the autumn of 1889, to extend the operation of muzzling to Lancashire, the West Riding of Yorkshire, Cheshire, and some other districts where rabies was prevalent. The results of this action were very satisfactory, as the cases reported for Great Britain fell from 312 in 1889 to 129 in 1890; were still further reduced to 79 in 1891, while in 1892 there were but 38 cases.[5]

With this great decrease in the prevalence in rabies, public interest and support waned and disappeared, while opposition to muzzling became so vigorous that the muzzling orders were withdrawn, and the matter left once more in the hands of the local authorities. The local authorities hesitated to incur the odium of making muzzling regulations, and, consequently, very little was done to control the disease. The result of this was plainly seen in the rapid increase in the number of cases reported. These were as follows: 1893, 93 cases; 1894, 248 cases; 1895, 672 cases.[6]

This condition of affairs opened the eyes of the English people, and strong and increasing pressure was brought to bear on the Board of Agriculture to deal with rabies in a thorough manner. In 1896, public alarm had caused the local authorities to be somewhat more rigorous in the enforcement of muzzling, and following this the number of reported cases dropped to 438; but, with the abatement of the alarm, the enforcement of this measure was again neglected, and it became evident that there was danger of the disease increasing. The Board of Agriculture, therefore, issued the rabies order of March 23, 1897, withdrawing the power of making muzzling regulations from the local authorities, and imposing these regulations by central authority. Inspectors were employed to make searching investigation in every case, to trace the dogs which might have been bitten, to secure their slaughter or isolation, and to determine the boundaries of districts to be placed under muzzling orders. These inspectors were also engaged in efforts to induce the local authorities to seize and destroy ownerless and stray dogs.[7]

It was frequently urged, says the report, that rabies was by no means so prevalent as it was supposed to be, and that many of the reported cases were not true rabies, but some affection which temporarily produced symptoms which were mistaken for that disease. That is, England also had its Dulles and its Haines to cast doubt upon the diagnosis, and to obstruct the enforcement of the regulations. With a view, as far as possible, to eliminate all doubtful cases, and to enable the board to decide whether the muzzling regulations should be applied to, or withdrawn in, certain districts, a most exhaustive inquiry was made into the history of every dog killed as suspected. If there still remained a doubt, whether the slaughtered dog was or was not rabid, inoculations were carried out to decide the question.[8]

Now, we will see the result of these thorough measures. Starting with 438 cases in 1896, the number was reduced to 151 in 1897, to 17 in 1898, to 9 in 1899, and to 6 in 1900. In the year 1900, there was not found a single rabid dog in England or Scotland, the six cases reported having developed in South Wales, a district which, by reason of its mountainous nature, renders it extremely difficult to enforce a muzzling regulation, and where dogs affected with rabies may easily wander from their homes and die in some remote place without recognition.[9]

Now, if Dr. Dulles is correct in his conclusion, that rabies is not a specific disease, and that it is about as likely to follow the bite of a healthy as of a rabid dog, will he, or some one else, explain how it can be stamped out of countries like England and Scotland by muzzling dogs in districts where the disease appears, and by slaughtering the dogs which are rabid, or which have been bitten by rabid

animals? The muzzling orders are only applied temporarily and in certain districts where the disease has appeared. There were but two rabid dogs in England and Scotland during 1899, and none during 1900; consequently, for two years there has been but little muzzling. The dogs of these countries were, therefore, as free to bite as they were before any regulations were made, but there have never before been two years with such freedom from rabies since records of the disease have been kept in Great Britain. This result, to my mind, is sufficient in itself to disprove absolutely the position which Dr. Dulles has assumed, and which the medical profession has fortunately viewed with disfavor, notwithstanding his special pleading for many years.

There remains one more point of great interest, which should be brought out in this connection. What has been the effect of eradicating rabies in dogs in Great Britain upon the development of rabies in man? Dulles, Woods, Haines, *et al.* have been telling us for years that the so-called hydrophobia of man was mostly or entirely lyssophobia. That it was produced by fear after having been bitten by a dog, or that, at the worst, it was not a specific disease. If this were true, there should have been no diminution in the number of cases of hydrophobia in man; on the contrary, according to the reasoning of these gentlemen, the number of cases should have been increased by calling attention to the malady in enforcing the muzzling orders, just as they claim that it has been increased by the influence of the Pasteur treatment. But no such result has followed. The disease in man has steadily decreased from 1895, when there were twenty deaths, to 1899, when, for the first time in over half a century that is covered by the records, there was a year without a death from hydrophobia in England and Wales. The year 1900 also is reported to have passed without a death from this disease.[10]

Is this a mere coincidence, or does it prove that rabies is a specific disease? And as it is only a repetition of the experience of Norway, Sweden, and Holland, does it not indicate that such a result will probably follow in every case?

I have gone into details concerning the history of the eradication of rabies in Great Britain, and have taken my statements, almost word for word, from the official reports, because the matter has been so frequently misrepresented in the press of this country. With the rapid increase of rabies in the United States, it is time that the medical profession, at least, should know the facts.

Dr. Dulles makes an amusing attempt to prove that there were more deaths in Paris from hydrophobia during the five years succeeding the inauguration of the Pasteur treatment than during the five years preceding it. This is how he does it. He takes the statistics of Dujardin-Beaumetz and arranges them as follows:

Lustrum preceding:		Lustrum following:	
1880	4 deaths.	1885	22 deaths.
1881	21 "	1886	3 "
1882	9 "	1887	9 "
1883	4 "	1888	19 "
1884	5 "	1889	6 "
Total	43 deaths.	Total	59 deaths.

If he had not made an error in copying the figures for 1884, which should have been 3 instead of 5, he would have had a still more striking contrast. The deception in this table is in putting the year 1885 after the inauguration of the Pasteur treatment, instead of before it. As there were more deaths in this year than in any other year covered by the table, it forms a convenient means of changing the result. The Pasteur treatment did not begin until November 1, 1885, when five-sixths of the year was passed, and when it was too late for the treatment to have any marked effect upon the cases of hydrophobia during that year. A single case was treated before the method was offered to the public, but as information concerning this case was not given out until October 26, 1885, it does not affect the general statement just made. Now, if we put the year 1885 in the period preceding the beginning of the treatment, as in all fairness it should be placed, we have:

5 years preceding:		5 years following:	
1881	21 deaths.	1886	3 deaths.
1882	9 "	1887	9 "
1883	4 "	1888	19 "
1884	3 "	1889	6 "
1885	22 "	1890	1 "
Total	59 deaths.	Total	38 deaths

As a matter of fact, the largest number of deaths from hydrophobia occurred in the years in which there were most rabid dogs, and as there happened to be a considerable increase in canine rabies in the years following the beginning of the Pasteur treatment, the mortality from rabies did not decrease to the extent that it otherwise would have done. It is naïvely remarked by Dr. Dulles in reference to the year 1885, that it was "the year in which the Pasteur method was brought out, when the largest advertisement of it was made in the newspapers of Paris, when everybody was talking about it all over the world, and when cases of lyssophobia multiplied everywhere in consequence of this morbid discussion. So marked was the increase in deaths from rabies among animals at this time in France that I find Nocard, in 1888, speaking to the Academie de Médecine of Paris of the cases occurring in Paris, says that a like increase was observed everywhere in France; while in 1892 Galtier declares to the same body that hydrophobia has singularly increased."

Does Dr. Dulles intend to convey the impression that this increase of rabies in dogs was really lyssophobia developed in consequence of the "morbid discussion?" If not, it is difficult to see what idea he expects the reader to gather from the fact stated in this connection. There appears to be no other way of charging the Pasteur treatment with responsibility for the increase of canine rabies.

Again, Dr. Dulles quotes statistics as to the number of rabid dogs in Germany from 1889 to 1894, showing but one case of hydrophobia in man to 435 cases of rabies in dogs. In France, he finds by an indirect method, which I shall not attempt to controvert, that "on the most moderate estimate of the ratio of mortality to bites accepted by the Pasteur Institute, this would have furnished 516 deaths, if untreated, or one to about twelve cases in dogs." From this he proceeds to argue that "there is an enormous discrepancy between the ratio of deaths from hydrophobia to cases of rabies in dogs in Germany and that in France—the latter having a mortality thirty-eight times as great."

It is intimated that this great disparity exists between France and other countries—England, Belgium, Holland, and Austria. As Holland has long been free from hydrophobia in man and rabies in dogs, there are no recent cases to compare. It will,

however be interesting to compare the figures as to England and Wales for a series of years.

TABLE SHOWING HUMAN AND CANINE RABIES IN ENGLAND AND WALES.

Years	Cases of Human Rabies.	Cases of Canine Rabies	Ratio between Human and Canine Rabies
1887	20	217	1 : 7.48
1888	14	160	1 : 11.43
1889	30	312	1 : 10.40
1890	8	129	1 : 16.12
1891	7	79	1 : 11.20
1892	6	35	1 : 5.83
1893	4	45	1 : 11.25
1894	13	210	1 : 16.53
1895	20	668	1 : 33.40
1896	8	434	1 : 54.25
1897	6	150	1 : 25.00
1898	2	17	1 : 8.50
1899	0	0	....
1900	0	6	....

This table shows in several years for England and Wales a narrower ratio than has so surprised our controversial friend when found in France.

I am inclined to think that the strictly enforced muzzling regulations in Germany are a sufficient explanation of the differences which are found in the ratio of that country as compared with France and England. Consul-General Mason, who was asked by the State Department to investigate and report upon the matter, said: "In Berlin, Frankfort, and, so far as I know or can ascertain, in all cities and large towns in Germany, dogs are required to be muzzled whenever they are on the street or public place, and this regulation is enforced in cities even when the dog is led or held in leash by the owner, or is harnessed for working purposes to a cart or other vehicle."[11]

In England, the muzzling was only required temporarily, and was confined to infected districts. In Germany, it appears to be universal, at least in all the centers of population. In France, as in the United States, muzzling is infrequent, spasmodic, and has little effect on the number of cases of rabies in man or animals. Dr. Dulles alleges that the muzzling laws "of Germany do not prevent the taking up annually of a very large number of unmuzzled and suspected animals whose opportunities for biting are quite sufficient to cause a large number of deaths from hydrophobia." The first thought that suggests itself, in this connection, is: If the bite of a healthy dog is as dangerous as the bite of a rabid dog, as Dr. Dulles believes, why are there not a larger number of cases of hydrophobia in Germany? He does not attempt to explain this inconsistency in his own argument.

The fact is, where muzzling is universally required, the appearance of a dog without a muzzle at once attracts attention, and is a warning to people that something is wrong with it. The capture and slaughter of unmuzzled dogs prevent the accumulation of ownerless animals, which in other countries are an especial menace, because they often wander miles daily, searching for food, and are more apt to be bitten than are the pets of the household which are kept upon the owner's premises. While, therefore, a certain number of unmuzzled dogs are captured annually in Germany, that fact is not an argument against either the specific nature of rabies, or the value of muzzling regulations in protecting human life.

Undoubtedly, the statistics of the Department of the Seine collected by Dujardin-Beaumetz are the most accurate which we have from any district in France as to the number of cases of human and canine rabies. These statistics indicate that the ratio between these cases in France and Germany does not differ to anything like the degree which Dr Dulles thinks. The following table which I have compiled, is conclusive on this point.[12]

Years.	Human Rabies	Canine Rabies	Ratio between Human and Canine Rabies.
1881	21	615	1 : 29.28
1882	9	276	1 : 30.66
1883	4	182	1 : 45.50
1884	3	301	1 : 100.33
1885	22	518	1 : 23.54
1886	3	604	1 : 201.33
1887	9	644	1 : 71.55
1888	19	863	1 : 45.42
1889	6	367	1 : 61.16
1890	1	203	1 : 203.00
1891	4	400	1 : 100.00
1892	5	676	1 : 135.20

The above table shows that the large number of cases of hydrophobia in 1885 corresponds with a large number of cases of canine rabies, and that the ratio was only slightly narrower than in 1881 and 1882, and not nearly as narrow as in England in the years 1887 to 1894, inclusive. It also shows that, while the statistics for the year 1885 alone might appear to furnish some ground for the conclusion that "cases of lyssophobia multiplied everywhere," if we take into account the fact that the Pasteur treatment was not commenced until near the end of that year, that the discussion of it was more general and more excited in 1886 than in 1885; that about 2,700 patients were treated in 1886 as compared with about 150 in 1885; and, finally, that there were but three cases of hydrophobia in 1886, the argument falls to the ground. If there were a large number of cases of lyssophobia in 1885, there should have been, on the same line of reasoning, a still larger number in 1886. But this was one of the years in which the cases of hydrophobia were at a minimum, and the cases of canine rabies were large, and, consequently, when there was the largest number of canine cases to each human case with a single exception in the series of twelve years. There is no indication of lyssophobia here.

The table also shows that the Pasteur treatment has had a favorable effect upon the ratio of human and canine rabies. Taking the four years (1881–1884) preceding the year in which the treatment was commenced, the ratio was 1 : 37.13: in the four years (1886–1889) following the one in which the treatment was commenced, the ratio was 1 : 66.97: in the last three years covered by the table (1890–1892) the ratio was 1 : 127.9. This appears to be progress in the right direction, and certainly does not warrant Dr. Dulles' pessimistic remarks.

Time sets all things right, and Dr. Dulles may have observed that at Berlin, where Pasteur's views were once questioned and combated, there has been established a department for the protective inoculation against rabies in connection with the Royal Institute for Infectious Diseases. In the last report of the work at this department it is stated that in 1898 there were treated 137 bitten persons with no deaths. In most of these cases, rabies was clearly established in the dogs which did the biting. In 1899, there were treated 196 persons with no deaths. The treatment lasted nineteen to twenty days, according to the Paris method.[13]

It appears, therefore, that this royal Prussian institution is strictly following the Pasteur treatment, and that for two years the result has been perfect protection of the bitten people. I see no escape from the conclusion that this report absolutely vindicates the Pasteur treatment, if it needed any vindication. There may be some men who will not be convinced this side of the grave; but physicians, at least, owe it to their profession to abstain from such villification of Pasteur and his followers as appeared in the paper under discussion

It should scarcely be necessary to remind a lecturer

on the history of medicine that the medical profession came well on to the three-quarter-mark of the last century in the densest ignorance of the cause and nature of contagious diseases. No one knew whether these diseases were due to electrical or other disturbances of the atmosphere; to peculiarly subtile chemical poisons; to perverted protoplasm; to bacteria, or to some absolutely unknown force of nature. The subject was the *bête noire* of medicine. But, fortunately, the researches of Pasteur on fermentation and on silkworm-diseases pointed the way out of this desperate situation. They led to the work of Lister, of Tyndall, of Koch, and to the later work of Pasteur on chicken cholera, septicæmia, anthrax, and rabies—researches which not only placed the germ theory of disease upon a scientific basis, but which put within our grasp the most unexpected resources in the way of prevention and cure.

Pasteur was one of the greatest investigators the world has produced; he was unmercifully criticised because his views were so original and so astonishing; but his principal conclusions have been accepted by other investigators because they have been confirmed and are right. It is useless for Dr. Dulles, or any one else, to try to disprove facts which are so firmly established, and it is far from edifying to read slanders based upon newspaper clippings of this great man, to whom we owe so much, and who, in his grave, is certainly entitled to respectful treatment.

SOME FACTS LEARNED IN THE MANAGEMENT OF TYPHOID FEVER IN CENTRAL WEST VIRGINIA.*

BY W. W. GOLDEN, M.D.
ELKINS, W. VA.
SECRETARY OF THE WEST VIRGINIA STATE MEDICAL SOCIETY.

THE great frequency of typhoid fever in spite of the great advances in sanitation on the one hand, and the absence so far of any specific means for its early abortion on the other, must make the subject of its treatment always interesting. Until the labors of so many able workers in the fields of the newer therapies are crowned with better success than they have hitherto been, the treatment of this disease on old and well-tried lines must continue to engage our attention, and the observations of the individual physician at the bedside under the varied conditions of private practice should still have some value. And this value need not be necessarily by virtue of some new discovery or invention, for the corroboration and reaffirmation of facts already known may prove of even greater benefit to our art by adding to the strength of our occupied positions and enabling us to resist the attacks of the spirit of innovation, which often, alas, too often, smacks of sensationalism more than of true progress.

In an article published by the late Dr. James E. Reeves, who was then practising in the historic town of Philippi, in the *Buffalo Medical Journal* for October, 1856, he traces the introduction of typhoid fever into Central West Virginia to a case brought there from Ohio under the name of "slow fever" in 1837. For some reason the infection of the disease found a fertile soil there, and a very extensive epidemic soon followed, as recorded by Reeves in his analysis of 110 cases. As this part of the State figured largely as a battlefield and camping ground during the Civil War, it has shared the fate of all such places in becoming a hotbed of many infectious diseases, notably of typhoid fever. The recent rapid development throughout the State of very extensive mining and lumber industries, with their usual attendant unsanitary camps and hastily constructed villages, has added considerably to the further spread and perpetuation of the disease under discussion. You will, perhaps, grasp more fully the force of this development as a factor in the etiology of this disease, if I call your attention to the fact that the great increase in the population which has accompanied this development has been mainly by the influx of younger persons, between the ages of twenty and thirty, a period of life well noted for its great susceptibility to typhoid fever. The disease has thus become there endemic, prevailing epidemically during certain months of the year; but sporadic cases can be found all the year around. The experience, therefore, of physicians with this disease is very wide. I believe that I shall probably underestimate it, if I state that fully one-fourth of the medical practice in Central West Virginia consists of attendance upon cases of typhoid fever. A very noticeable abatement of the disease, however, has taken place in the last few years in many of the towns which have profited by their sad experience in the past, and have not spared their money in constructing public water works, sewers, and many other sanitary improvements. Of these I shall mention as good examples the towns of Elkins, Davis, and Belington.

The clinical picture of the disease there does not differ from what I have seen it to be elsewhere. The classical textbook type of the disease is met with, but more often its course is atypical in many ways. Constipation is more common than diarrhœa. The eruption is seen only occasionally. An unduly high temperature at the beginning is frequently seen, but is mostly due to the heavy diet indulged in by the patient with the hope of overcoming his growing weakness before seeing his physician. A good cathartic usually brings the temperature down to its legitimate level. A failure to relieve the headache of the first week by means of the coal-tar derivatives, and the disproportionately free response of the bowels to cathartics, even in cases otherwise characterized by constipation, have come to be considered there as pathognomonic therapeutic tests of no little value. Complications are not very common, but are great in variety. Relapses and recrudescences are exceedingly common even under the most judicious treatment and best nursing.

The duration of the disease will average about four weeks, with an occasional minimum of eight days and a maximum of seven or eight weeks. The mortality average is comparatively small and will not much exceed 6 per cent. In the practice of some individual physicians it is much lower than that. In my own practice it has so far not exceeded 2 per cent. during a period of nine years. Most of the fatalities are due to hemorrhage, and there are on record epidemics which were noted for the great fre

*Read before the Tri-State Medical Association of Western Pennsylvania and Maryland and West Virginia, July 25, 1901.

quency of this complication, as well as such which were noted for freedom from it. The fatal cases not due to intestinal hemorrhage are mostly caused by perforation, a death from exhaustion being exceedingly rare. I must add that these observations are based as much upon practice among the newer elements of the population, drawn from all parts of the country and from abroad, as upon the practice among the native and pioneer classes. As of special interest I will mention the common knowledge there of the existence in some places of fixed foci of typhoid infection. The public has learned to dread these typhoid-fever houses. As an illustration I will mention the instance of one boarding house in which typhoid fever has been the curse of its occupants for the last ten years. The house has undergone many renovations and alterations in structure at the hands of its several successive owners, its water supply has been changed, and some improvements have been made in the drainage of its ground, which was bad for a while; but all this has made no noticeable change in its apparent infectiousness. Time and again there have been cases of typhoid fever in that house when there was none known in the town, either at that time or for some time preceding it. The cases which occurred in it from time to time were also noted for their great severity.

I have learned to look upon the regulation of the diet as to kind and quantity as the most important part of the management of typhoid fever. In common with others, I have found cow's milk to be the safest article of food in this disease, and at the same time fully sufficient. Prior to 1898, such a statement before such an audience would have appeared so commonplace as almost to need an apology. But since the diet-reform wave was started at St. Petersburg, it has made such rapid progress across this continent that what one really fears in making such a statement is contradiction. I have never prescribed for my typhoid cases much else outside of milk as a food, but time and again a disobedient patient on his own initiative, or at the suggestion of an overanxious member of his family, has tried the Bushyev experiment for himself. As a rule, every such indulgence ended most disastrously. There is hardly a practising physician in Central West Virginia who cannot recall more than one instance in his practice in which relapses far exceeding in severity the initial attack, and not infrequently resulting in death, have followed the ingestion of such articles as soft-boiled eggs and toasted bread only. One of the severest relapses I have seen myself followed within a few hours the ingestion of a piece of toasted bread not larger than the size of my thumb, after a normal temperature had existed for forty-eight hours. Even the general public has learned to recognize the greater safety of an exclusive milk diet. If, as is fortunately only very rarely the case, a patient is unable to take milk, I always expect a troublesome time, and subsequent developments have always proven the justification of such an apprehension. Patients who first object to a milk diet are rather common; but there are very few, indeed, who continue their objection after a few days' fasting, which I believe to be of some advantage. My special concern in the treatment of typhoid fever comes with the time in the stage of convalescence for a change of diet. Until all the symptoms of the disease have subsided, and the faeces have become perfectly normal in every way, I have learned to look upon any radical change in the diet as a very dangerous experiment. The advice given by conservative authorities to postpone a change from the milk diet until eight or ten days of convalescence have passed, I believe, to be a most excellent one. I have found that in such cases, when the confidence of the patient in me was a little stronger than the craving of his palate for a change in his menu, I have been able to restore him to his flesh and strength much sooner by continuing him on a milk diet for two weeks after he had become convalescent than when a more liberal diet had to be allowed earlier. I have repeatedly had occasion to test the effect of a continued but abundant milk diet on the one hand, and that of a mixed diet on the other, upon the rate of recuperation during convalescence in members of the same family whose cases have run a parallel course. The advantage was markedly and invariably in favor of the milk. True, once in a while I have seen a person suffering from typhoid fever who took his case in his own hands, and, while going about his business, was keeping himself on a diet that surpassed in coarseness that of Bushyev, Moorehouse, and other recent followers of Graves, and who yet fully recovered without any apparent bad results. But I should no more think of taking such instances as an argument in favor of allowing my patients a more liberal diet than I should in favor of allowing them to exercise, although it would seem that Wilson has actually done so when he advocates the permission of typhoid-fever patients to walk from their beds to the bathtub. Buttermilk I have found a safe substitute for milk. I have never seen any harm from the use of some lemon juice in waters.

The regulation of the quantity of food I have found to be of equally great importance. It is safer and wiser to underfeed than to overfeed. I have time and again succeeded in changing the course of the disease from malignant to benign by withholding all food for a while.

The tendency among physicians is to overfeed their typhoid patients. In fact, there is a tendency to overdo things in many other respects. Increasing experience and observation are impressing me with the greater importance of learning what to avoid than what to do in these cases. The late Dr. Loomis used to say that, if he were a sufferer from typhoid fever, all he would want would be a quart of milk in twenty-four hours, the cold coil to his abdomen, and to be left alone. He evidently had great confidence in nature's power. Yet, it would have greatly added to his safety in such a case had he upon him in addition the watchful eye of a conservative physician in a state of "armed neutrality." I find it best not to allow any order for the quantity of milk to be given to hold for a period longer than the intervals between my visits. In fact, I find it of great advantage to vary the quantity from time to time, and to this end I devote much of my time at each visit to a study of indications. Given a case of a patient with a fair degree of energy and flesh in reserve, a dry mouth and a high temperature indicate a minimum of food. Such cases will do better when the quantity of milk does not exceed one pint in twenty-four hours, if a larger quantity of water be given along with alcohol in doses so small as to produce no perceptible stimulation, but frequently administered. Diarrhœa indicates spare feeding. The morning hours, the stages of development and decline call for larger feeding, while during the afternoon hours and during the fastigium the quantity is to be reduced.

The enthusiasm of the earlier days of my professional career has given way to maturer judgment, and many a beautiful theory regarding the abortion of the disease has been killed by the ugly facts gathered at the bedside. Inasmuch as the duration of the disease varies greatly when entirely without any treatment, what process of logic can convince us that a certain drug or combination of drugs has any other relation to the short duration of a given case than that of mere coincidence? The rapid recovery might

have occurred independent of the remedy used, either because of a high degree of individual resistance (*i. e.* either a high degree of Metchnikoff's phagocytosis, or the power of producing large quantities of Ehrlich's antibodies, and Büchner's alexins in response to toxic stimuli) on the part of the patient, or because of the mildness of the attack. The mildness of the attack might have been due to some climatic, seasonal, or more subtle feature in the environment, exercising an inhibitory influence upon the vitality, and, hence, also upon the virulence, of the specific bacilli. For what is true in the macroscopic world must also be true in the microscopic one, and if variation—physical, chemical, and physiological—in consequence of the law of adaptation, is the law in the higher planes of the biological world, the same must prevail in the lower ones, such as are included in the generic name of pathogenic bacteria. We could not, therefore, even by *a priori* reasoning, expect that the effects produced by the implantation of the Eberth bacilli should be alike in all cases. However, much can be done by means of medicinal treatment toward the prevention of complications and unessential symptoms. Tympanites is an undesirable and unnecessary symptom; but if a correct diet has been followed, one seldom sees it excessive. But with the daily use of an enema of saponified water, holding in emulsion 1 drachm of oil of turpentine, the distention of the intestine will hardly ever exceed the normal. I have, therefore, made it a routine treatment and consider its use only next in importance to the diet. The only contraindications to its use are the occurrence of hemorrhage or perforation. Of all the internal antiseptics I have some faith in thymol. It does seem to contribute toward a better intestinal condition. I may mention right here that the Woodbridge treatment is generally condemned in central West Virginia.

RUPTURE OF THE URETHRA.

A Report of Cases.*

By JAMES R HAYDEN, M D.
NEW YORK

The serious nature of urethral rupture, the importance of its early recognition, and the prompt employment of such treatment as will check urinary extravasation and prevent the subsequent formation of stricture, will, I trust, render a recital of the following cases of practical interest, and, at the same time, elicit free discussion as to the most suitable method of treating this grave, and not infrequently encountered, condition.

Case I.—Thirty-six years of age. Has never had any disease of the genito-urinary organs. About thirty hours before admission to Bellevue Hospital, and while in an intoxicated condition, patient was kicked in the perineum, his assailant wearing a heavy sea boot. The next day, when he awoke from his debauch, he noticed blood on his shirt, and a slight bloody discharge from the meatus. On attempting to urinate, he had an intense burning pain in the glans, and a feeling as if the urine was "leaking" into the perineum and penis. The stream was very small, forked, and dribbling, and patient had to strain for some time in order to start it. The act of urination caused such severe pain that he broke out in a profuse perspiration and fainted. Patient went through this same experience each time he attempted to empty his bladder, and finally became so weak and exhausted that he entered the hospital for relief.

Examination on Admission.—Temperature, pulse, and respiration normal. The perineum is greatly swollen, tender, fluctuating, bluish-black in color, and abraded in places. The prostate and adjacent parts are normal by rectal touch. There is a slight bloody discharge from the meatus. The urine is tinged with blood and contains bloody shreds, but is normal in other respects. No stricture of the urethra detected, but the bulbous portion of the canal is exquisitely tender, bleeds freely, and feels roughened and lacerated. There is some compressor spasm, which is readily overcome by gentle pressure.

A diagnosis of rupture of bulbous urethra, with beginning extravasation of urine being made, the patient was etherized and external urethrotomy performed in the usual manner. The perineal tissues were found extensively infiltrated with blood clots, and a thin bloody fluid having a distinctly urinous odor. The bulb of the corpus spongiosum was crushed into a bleeding and oozing mass of tissue, the bulbous urethra being ruptured longitudinally in many places on its floor, while its roof remained uninjured. The clots were turned out of the perineum, and all bleeding points ligated. A full-sized sound was passed from the meatus, and the bladder irrigated and drained by a large perineal tube, which was removed permanently on the fifth day, and full-sized sounds passed every other day until the perineal wound was healed.

The patient convalesced rapidly and left the hospital at the end of twenty days, the perineal wound being completely cicatrized, and the urine passing normally by the meatus.

No attempt at suturing the urethra was made on account of the contused condition of the tissues, the multiplicity and nature of the wounds, and the integrity of the roof of the canal.

Case II.—Thirty-seven years of age. Twelve years ago patient had urethritis, which was apparently cured. Twenty-four hours before admission to Bellevue Hospital, and while at work carrying a fifty-pound weight on his shoulder, patient fell ten feet, landing astride a two-inch iron pipe. On standing up, he felt very wet about the genitals, and on inspection found that he was bleeding freely from the meatus, but had very little pain. Patient went to his home in a street car, and called in a physician, who failed to enter the bladder after prolonged and painful instrumentation, and then, in order to stop the hemorrhage, tied a bandage tightly around the penis.

Examination on Admission.—Twenty-four hours after accident: Temperature 102° F., pulse 72, respirations 24. Patient is very weak and anæmic from loss of blood, but not in much pain, except that due to urinary retention, which has not been relieved since the accident. The prostate and neighboring tissues are normal by rectal feel. The anterior abdominal wall is very tense and rigid, and the bladder greatly distended. The penis is so tightly bandaged as to cause marked swelling of the glans, which looks almost gangrenous. On removal of the bandage, a surprisingly large amount of blood spurted forcibly from the meatus, but even then the patient was unable to urinate voluntarily.

Scrotum and perineum greatly ecchymosed, the latter being distended, tense, and fluctuating.

A diagnosis of rupture of the urethra with urinary extravasation being made, the patient was prepared for operation and etherized. Soft-rubber and silk catheters passed as far as the bulbous urethra, where they apparently left the canal and entered the perineal tissues. A No. 20 French silver catheter was passed into the bladder by keeping its tip in close contact with the roof of the canal, which

*Read before the American Association of Genito-Urinary Surgeons, Old Point Comfort, Va., May, 1901.

was apparently intact. Forty-two ounces of bloody urine and many clots were evacuated, and the bladder irrigated with hot saline solution, several ounces of which were left in. During these manipulations the hemorrhage from the meatus was quite free.

The patient was then put in the lithotomy position, and external urethrotomy done, using the silver catheter as a guide. The perineal tissues were filled with bloody urine and clots, and oozing freely. When the bleeding was stopped and the parts dried, a longitudinal rupture about two inches in length could be seen in the floor of the bulb of the urethra. A full-sized sound was passed to the bladder, which was irrigated and drained by a large perineal tube as in external urethrotomy. The perineal wound was left open and lightly packed with gauze. On the fourth day the perineal tube was removed permanently, and a No. 30 French sound passed to the bladder.

On the twelfth day the wound in the urethra was cicatrized, all the urine passing by the meatus after that day.

The perineal wound was closed at the end of the third week, the patient remaining in hospital for several weeks longer for irrigations, sounds, and observation.

In this case, the urethra looked so swollen and boggy that no attempt at closing the rent in the floor was made, especially as its roof and walls were intact.

At the present writing, which is a little over a year after the operation, urination is normal, the patient taking a full-sized sound with ease.

Case III.—Thirty years of age. Admitted to Bellevue Hospital December 19, 1900. Patient had a very slight attack of anterior urethritis nine years ago. About twelve hours before entering hospital, and while intoxicated, patient says he fell a considerable height from a gangplank, landing astride a narrow board; he was able to get up without help after the accident, in spite of the severe pain in the perineum. Six hours later, on urinating, he found his underclothes stained with blood, and the meatus sealed with a dry clot, on removal of which urination was free, but painful, and followed by bleeding, which so frightened him that he entered hospital for treatment.

Examination on Admission (twelve hours after injury).—Temperature, pulse, and respirations normal. There is a slight and constant oozing of blood from the meatus; the urine is tinged with blood, and contains a few, light bloody threads and flakes, but is normal in other respects. Urination is free, but painful. The perineum is ecchymosed and slightly swollen and tender, but there is no local point of tumefaction or fluctuation. Prostate and surrounding structures normal by rectal touch. A large soft-rubber catheter enters the bladder with ease and draws clear urine; the urethra feels normal, although the bulb is exquisitely sensitive. A diagnosis of rupture of the bulbous urethra without extravasation being made, the patient was put to bed and given boric acid in full dose; he was catheterized at regular intervals with soft-rubber instruments, and the urethra very gently and sparingly irrigated at these times with a warm sterile alum solution; the perineum being covered with a cold bichloride dressing, and the temperature and pulse taken every two hours, to keep us informed as to the necessity for external urethrotomy and vesical drainage.

On the fourth day all bleeding had stopped, the urine being perfectly clear, and the perineal swelling having disappeared. The temperature has remained normal since admission.

On the fifth day the patient was up and about, and passing a clear urine in a perfectly normal manner.

On the tenth day the patient left the hospital at his own request, as he felt perfectly well and was anxious to resume his work.

In conclusion, it may be broadly stated that the treatment of rupture of the urethra is either operative or non-operative in character, depending upon the nature and extent of the injury, which, as a rule, can be readily ascertained by a careful study of the local conditions.

If there is marked hemorrhage from the meatus with a complete retention of urine, or difficult and painful urination and bloody urine, associated with difficulty or inability to enter the bladder with instruments; and, also, if there is a fluctuating perineal tumor, with perhaps a rise of temperature, then immediate perineal section and bladder drainage are indicated.

If, on the other hand, hemorrhage is slight, urination free, but somewhat painful, the urine tinged with blood, or containing light bloody flakes, and catheterization normal, except perhaps causing some pain at a localized spot, which feels slightly roughened or thickened, and little or no perineal tumefaction, then catheterization, irrigation, and urinary antiseptics should be resorted to, the patient in the meantime being kept in bed, and carefully watched for the first sign of urinary extravasation, in the event of which external urethrotomy with vesical drainage should be immediately resorted to.

Partial suture of the urethra must always be employed in case of complete rupture, in which the divided ends of the canal are widely separated; otherwise it is not essential.

Complete suture of the damaged canal is, in the writer's opinion, contraindicated, as it prohibits the free bladder and urethral drainage, which is so essential for the contused and infiltrated condition of the tissues in these cases.

OPERATION FOR CARIES OF THE MASTOID, SECONDARY OPENING OF THE LATERAL SINUS, AND LIGATION OF THE INTERNAL JUGULAR VEIN.

By JULIUS ROSENSTIRN, M.D.,
SURGEON TO MT. ZION HOSPITAL,
SAN FRANCISCO, CAL.

The cases of mastoid disease with infectious thrombosis of the lateral sinus and extension of the process into the jugular vein are sufficiently rare and interesting to warrant the publication of the following case: The patient, I. S., fifteen years old, came under my care August 7, 1899. The family history was negative, and the patient had always been well. He first noticed pain in the right ear four weeks before entering the hospital. He had never suffered from any running of the ear. Simultaneously with the pain, swelling appeared behind right ear. Two weeks subsequently he complained of severe headaches, was thirsty and feverish in the evening, but had no dizziness or nausea. There was a large swelling extending from the level of the concha down to 3 cm. below the mastoid process, commencing in the region directly behind the ear and extending backward 2 cm. behind the posterior border of the mastoid process. The swelling was very painful to the touch, and gave indistinct fluctuation; the skin was reddened over it. The ear was discharging a foul-smelling pus, the tympanum was perforated, and there were some granulations in the meatus externus. The watch

was heard only at the meatus. Bone transmission on the mastoid was impaired, but was normal on the top of the head. Slight somnolence of patient prevented a satisfactory examination. Immediate operation was advised and consented to. After the usual preparation, an incision was made commencing behind the concha of the right ear at the level of the upper margin of the helix, describing a semicircular line around the ear downward to 1 cm. below the mastoid process. The incision was carried down to the bone, the periosteum and soft parts being pushed back with an elevator. During this part of the operation, pus came from a perforation in the mastoid process. Careful curettage was begun, but hardly had the curette been introduced when a most profuse venous hemorrhage occurred. It was thought at the time that the hemorrhage proceeded from the lateral sinus, although anatomically we were not in that region, being too far anterior. Immediate digital compression was continued while the curetting was being done, until the granulations were removed and the bone surfaces were thoroughly cleaned and found intact. I then applied an iodoform-gauze tampon. I removed the diseased edges of bone overhanging the excavated part, and then opened the antrum. Syringing it failed to demonstrate a free communication with the middle and outer ear, for the boracic solution did not escape from the external meatus. The patient was put to bed, the usual dressing having been applied. That evening the temperature was 98.4°, pulse 80. The patient complained of pain in the head, and vomited a little.

On August 12, the patient complained of very severe pains on the right side of the head. The temperature at 8 A.M. was 98°, pulse 72; at 8 P.M. the temperature was 98.4°, pulse 78. The following day the wound was dressed, and when the tampon was removed severe hemorrhage occurred. This was controlled by a reapplication of the gauze tampon. At 8 P.M., the temperature was 103.6°, pulse 108. The ophthalmoscope showed normal conditions; the pupils were normal. Percussion of the head showed sligh sensitiveness over the temporal region.

On August 16, the patient complained of pain in the forehead. At 8 A.M. the temperature was 96°, pulse 92; at 8 P.M., temperature 100.6°, pulse 90.

On August 19, at 9.45 A.M., the temperature went up to 105.4°, the pulse to 115. The patient was sent to the operating room. Dr. Fischel kindly assisted me in the operation. An incision was carried back at right angles from middle of the original incision between 5 and 6 cm., down to the bone; the soft parts were retracted, and granulations that had formed in the meantime were curetted away. There was no suppuration, and the wound looked clean. The bone over the sinus was carefully chiseled off, until the knee of the lateral sinus was reached. The wall of the sinus looked pale, but showed no lesion. A Pravaz syringe was introduced, but aspiration brought only a little blood, not more than one or two drops. The wall of the sinus was opened, but no hemorrhage occurred, the sinus being empty. A very small curette was introduced in an anterior direction, but nothing was brought out. A curette introduced posteriorly removed a clot, 3 cm. long, followed by the usual profuse hemorrhage upon the opening of the sinus. The bleeding was allowed to go on for a few seconds. After packing with iodoform gauze, the wound was dressed and the patient was put to bed.

On August 19, at 3 P.M., the temperature was 100.4°, pulse 84. The following day at 8 A.M., the temperature was 98°, pulse 74. The headache and nausea had disappeared, but the patient complained of pain in the right anterior part of the neck. A slight œdematous swelling was discovered along the line of the internal jugular vein, where there was pain on pressure. It was decided to ligate this vessel. An incision was made 6 cm. in length, internally and parallel to the border of the sternocleidomastoid muscle. After isolation, the vessel was found to be empty. Ligatures were applied about 1.5 cm. apart, and a small piece of the vein was excised between them. A running suture of silkworm gut, covered with iodoform collodion, closed the wound. Recovery from this time was uneventful until September 11.

On September 11, the patient complained of a gland at the posterior margin of the sternocleidomastoid muscle, the size of a large almond, and very painful to the touch. Ichthyol was applied. On September 19, no change having been effected by the ichthyol, the small gland was removed by a transverse incision. On October 10 the patient was dismissed, well.

Zaufal was the first who, in 1880,[1] proposed a method to open and clear the sinus and also to ligate the jugular vein under certain conditions. In 1886, Horsley,[2] recommended the same procedure, which was first carried out in 1888 by Arbuthnot Lane. The literature on the subject of sinus thrombosis following infectious otitis media contains nearly exclusively chronic cases. Weissgerber,[3] in his paper on acute inflammation of the middle ear with sinus thrombosis, mentions the rapid course of his case as very rare when compared with the usual chronicity. His patient took sick on August 26, and was operated for the first time on November 14 of the same year, an interval of eighty days. Dahlgren[4] gave the history of a case of Lenander's, that was operated about seven weeks after the first appearance of ear symptoms.

Macewen's case[5] hardly ran two weeks from its inception to the time of its operation, but there the infection started from the diphtheritic pharyngitis traveling along the Eustachian tube, and the resulting secondary otitis media diphtheritica had been acquired along that road. In my case, only four weeks had passed from the time when the patient presented his first symptoms of sickness until I deemed an immediate operation necessary.

Barring, then, Macewen's observation, as not due to primary ear disease, my case shows the most rapid course of sinus thrombosis due to primary otitis media. Granting that a great many unsuccessful operations are not published, such very acute cases must be extremely rare and even Politzer,[6] whose range of observations equals that of any specialist, has recently stated that the sinus affection is incomparably more frequent in chronic than in acute cases. The extreme chronicity possibly is best illustrated by a case of Preysing's[7] in which a woman, seventy-four years old, had been suffering continuously for sixty years from a suppurative discharge from the ear due to cholesteatoma, and had finally developed a thrombosis of the sinus transversus (lateralis) with pulsating abscess of the sinus.

It is much to be regretted that through some accident it was impossible to make a bacteriological examination in my case, and the cause of infection therefore remained unknown. Speculation might point to influenza as being the most probable cause, but clinically there is very little support for such a view. The unusual hemorrhage encountered was due to a very large intraosseous vein filled to its utmost in consequence of the sinus thrombosis. Those veins are proportionately larger in juvenile skulls and empty directly into the sinus.

Figure 11 in Macewen's book shows the temporal bone of a fifteen-year-old boy with an abnormal

opening on its inner surface for a large vein emptying directly into the sigmoid sinus. Macewen's picture shows the left temporal bone, but according to Körner[9] these veins occur more often on the right side. According to the investigations of this author, the far greater frequency of sinus thrombosis after otitic disease on the right side is to be explained by the greater proximity of the carious focus to the sinus on the right than on the left side. His measurements show that the bone covering the right lateral (transverse) and sigmoid sinus in 77 per cent. of all cases is thinner on the right temporal than on the left, owing to the greater depth of the sinus on this side.[10]

These two conditions—the direct communication with the sinus of veins that pass through the diseased part of the bone and the greater proximity of this carious focus to the sinus walls, congregating on the right side—facilitate the infection and consequent thrombosis of the right sinus, and explain the preponderance over the left.

In cases where, at the time of operation, the infection and thrombosis extend already to the jugular vein, Jansen[11] calculates the danger of metastatic pyæmia and sepsis at 75 per cent.

The question of ligation of the vena jugularis interna in infection of the sinus enters here. Although the necessity of direct surgical interference in sinus thrombosis from otitis media is now universally conceded, Jansen[12] reports on forty-five cases observed in the Berlin otiatrical clinic, of which twenty-nine were operated upon without opening the sinus, with two recoveries, while sixteen cases with opening o sinus gave eight recoveries.

The advisability of simultaneous ligation of the internal jugular vein is yet disputed. Zaufal, Kröner, and Parker demand it. Jansen does not favor it. Macewen grants it only in those cases in which the jugular is directly involved. Jansen [3] has pleaded that thirteen of his cases of sinus operation without jugular ligation show eight recoveries (61.5 per cent.), while of the three with jugular ligation none recovered.

Körner[14] reports four recoveries in eight cases without ligation of the jugular vein, against nine recoveries out of twelve where the ligation took place. A. of Forselles[15] compiled 145 cases, of which twenty-nine had been operated upon. Thirteen without ligation of the jugular vein show 53.8 per cent. recoveries; sixteen with ligation, 62.5 per cent. Körner and A. of Forselles both compiled their series from the general literature on this subject, where the unfavorable cases are probably not so often recorded. Jansen's cases were all observed by him in his clinic, and therefore deserve greater consideration; but on their closer scrutiny they do not bear out the author's conclusions. His cases Nos. 122[16] and 106[17] admit a rather different interpretation, and in case 211 syringing from the cervical end of the ligated jugular veins might have freed the vessel of the infectious thrombotic masses and prevented the fatal infection. Macewen's[18] conservative views appear to be the safest to follow, especially as the ligation of at least the right jugularis interna does not seem to be free from serious danger. Linser[19] reported a case recently from v. Brun's clinic, where, in the course of an operation for goiter, adherent through previous inflammation, the right internal jugular had to be tied. Death occurred on the following day under symptoms of accelerated pulse, and respiration and great cyanosis. The autopsy showed that the cause of death was œdema of the brain, which occurrence was explained by the fact that the lumen of the left jugular and the diameter of the left jugular fossa were very considerably smaller than on the right. Extensive anatomical investigation by this author subsequently proved that one jugular foramen, generally the left one, is (by no means in rare instances) so much smaller than the corresponding one of the other side that the ligation of the larger vein imperils the circulation in the brain.

The author mentions two similar observations by Rohrbach (also v. Bruns' clinic) and by Kummer.

It did not surprise me that in spite of the sinus thrombosis the examination of the fundus of the eye did not reveal anything abnormal. Jansen[20] found papillitis in only 43.5 per cent. of his cases of pure sinus thrombosis. He missed it in cases of extensive thrombosis of the jugular vein, of the petrosal sinus, and even of the cavernous sinus, but found it in a case of slight thrombosis of the sigmoid sinus. This indicates that the disturbances of the blood circulation within the cranium are not responsible for the appearance of papillitis, but rather the filling of the arachnoid with liquor cerebri.

The cause of the glandular swelling and its connection with the otitic disease remained doubtful, but it was thought prudent to remove the gland, as no improvement occurred after a week's waiting, and application of ichthyol. The teeth on that side were sound. Microscopically the gland showed simply infiltration with lymphocytes and multinuclear and uninuclear leucocytes. Cultures showed no characteristic growths.

Nearly two years have elapsed since the patient left the hospital cured. I have seen him recently; there has been no discharge from the ear, and he is perfectly well.

Etiology of Nasal Polypi.—Irving Townsend says that it is wiser to accept the belief that polypi always indicate disease of the underlying bone than to continue the old practice of "lopping off the branches," by which method the patient is relieved temporarily of the mechanical obstruction caused by the growths, with the assurance that they will recur. In many cases it is possible to discover and remove the diseased bone and effect a radical cure, for "recurrence" depends on the failure to excise all the diseased tissue, and not on its peculiarity of structure or any inherent quality favoring reproduction. The relations of polypoid disease and suppuration of the accessory sinuses are not clearly defined, but are probably those of cause and effect, in which either may assume the active rôle, or both result from disease of the bone, as previously described.—*Homœopathic Eye, Ear, and Throat Journal.*

THE VALUE OF THE WIDAL REACTION IN THE DIAGNOSIS OF TYPHOID FEVER IN CHILDREN.

By MILTON GERSHEL, M.D.,
INTERNE MT. SINAI HOSPITAL
NEW YORK CITY

While the value of the Widal reaction is generally recognized and numerous statistics on cases in adults are available, it would appear that the value of the reaction in children has not been sufficiently emphasized, and that there are lacking statistics based on a large number of cases. It is a matter of common knowledge that typhoid fever in children, and particularly in young children, is apt to be atypical in its course and often difficult of diagnosis. Some of the causes of these difficulties are the following:

The temperature curve in children is apt to be irregular, or even intermittent; the date of the onset is very difficult to determine. Furthermore, in a number of cases the spleen is not enlarged, and the intestinal symptoms are mild or lacking.

A further cause of confusion is the frequency of enlargement of the spleen in anæmic and rhachitic children; and the frequency of enlargement of the spleen due to all varieties of enteric trouble, which condition, if the child suffers from prolonged fever, may give rise to an unwarranted suspicion that typhoid fever is present.

The data given in this paper are based upon the study of the fever cases occurring in the children's ward of Mt. Sinai Hospital in the service of Dr. Koplik from March, 1898, to October, 1901. The tests were made by Dr. Libman according to the method described in the Mount Sinai Hospital Reports, Vol. I.

A dilution of one to twenty was used in all cases. Where the Widal reaction came as a surprise, or, in other words, in cases in which typhoid fever had not been seriously considered, the reaction was repeated in the dilution of one to fifty. Such reactions were always positive. Dried blood was used for all the tests, except in a few cases where the Widal reaction remained negative throughout the course of typical cases of typhoid fever. Serum was then substituted for the dried blood with no different result. Altogether, 670 tests were made in 199 cases. Eighty-four of these cases were instances of typhoid fever, and the other 115 were febrile cases of the greatest variety, such as miliary tuberculosis, meningitis, pneumonia, endocarditis, septic conditions, etc.

In a number of these the existence of typhoid fever could not be excluded at the outset. In all cases, the Widal reaction was made daily until a positive reaction was obtained, or until the diagnosis had been cleared up by other methods.

In the 84 cases of typhoid fever we obtained positive results in 81. In all, 329 examinations were made. In these cases, repeated tests were necessary before 45 of the cases developed positive reactions, while 36 cases gave the reaction on the first examination. Our patients ranged between one and a half and fourteen years of age.

1	patient	was	1½	years of age.
4	patients	were	3	" "
9	"	"	4	" "
5	"	"	5	" "
10	"	"	6	" "
7	"	"	7	" "
5	"	"	8	" "
8	"	"	9	" "
6	"	"	10	" "
11	"	"	11	" "
8	"	"	12	" "
9	"	"	13	" "
1	patient	was	14	" "

Thirty-eight of these cases were males, and forty-six females.

The day on which the patient was noticed to be ill, or complained of being ill, was taken as the first day of the disease. According to this:

5	cases	gave a positive	reaction	on the	5th	day of	disease.
3	"	"	"	"	6th	"	"
3	"	"	"	"	7th	"	"
3	"	"	"	"	8th	"	"
4	"	"	"	"	9th	"	"
7	"	"	"	"	10th	"	"
26	"	"	"	between	11th	and 15th	day.
21	"	"	"	"	16th	and 25th	"
1	"	"	"	on the	26th	day of	disease.
1	"	"	"	"	27th	"	"
1	"	"	"	"	29th	"	"
5	"	"	"	"	30th	"	"
1	"	"	"	"	35th	"	"

Or, in other words, only 13 per cent. were positive by the end of the seventh day; 63 per cent., by the fifteenth day; and 89 per cent., by the twenty-fifth day.

In children, it is *a priori* probable that they have not suffered from a previous attack of typhoid fever. However, for the sake of accuracy, we include a separate table detailing the cases in which the reaction was positive only after negative results had been obtained. In these cases the possibility of the reaction existing from a previous attack of typhoid fever is absolutely excluded.

Among these,	4	were	positive	on the	5th	day.
	1	was	"	"	6th	"
	1	"	"	"	7th	"
	1	"	"	"	8th	"
	1	"	"	"	9th	"
	3	were	"	"	10th	"
	10	"	"	between	11th and 15th	days.
	16	"	"	"	16th " 25th	"
	8	"	"	"	26th " 30th	"

It will be of interest to compare these results with those given by other authors.

Morse[1] found that the reaction seldom appeared before the second week, and says therefore that the test is of little value up to that time. Musser[2] found the reaction in no case earlier than the seventh day, while in our series eleven cases had given the reaction by that time. Pfaundler[3] and Abelman[4], both reported their earliest Widals as occurring on the fifth day of the disease. Blackader,[5] from a series of forty-three cases of typhoid fever in children, reports, that

3	were	positive	on the	4th	day.
2	"	"	"	5th	"
2	"	"	"	6th	"
3	"	"	"	7th	"
2	"	"	"	8th	"
1	was	"	"	9th	"
3	were	"	"	10th	"
14	"	"	between	11th and	15th days.
12	"	"	"	16th "	25th "
1	was	"	on the	28th	day.

In other words, before the end of the second week he had obtained positive results in 70 per cent. of the cases—a figure which comes close to our own.

In no instance, among the 341 examinations made in the cases which were clinically not instances of typhoid fever, was a positive reaction ever obtained. On the other hand, as noted, three of our cases of typhoid fever never gave a reaction at any time. These cases were undoubted instances of typhoid fever clinically, as will be seen from their subjoined histories. These cases were very carefully watched, and repeated examinations made daily, the blood in the third case having been examined thirty-seven times.

Case I.—A. K., aged five years, admitted May 16, 1899. History of five days' standing; began with headache, fever, vomiting, and pain in the abdomen. Slight cough, no epistaxis. On ad-

mission, temperature was 104° F., pulse, 120; respirations, 30. Roscola present on abdomen and back. Lungs, heart, and liver, negative; spleen palpable, abdomen tympanitic, urine negative, except for the presence of diazo reaction. The temperature ran the typical course. The blood was examined eleven times, but the reaction never appeared. Discharged, cured, June 5, 1899.

Case II.—B. S., aged six years, admitted October 22, 1900. History of eight days' duration, beginning with headache, followed by fever and pain in the chest; bowels constipated, no epistaxis. On admission, chest, abdomen, and back were covered by a profuse roseola. Lungs, slight dulness with increased voice and breathing at the right apex. Spleen enlarged, and palpable one finger below free border of ribs. Abdomen otherwise negative. Leucocyte count, 8,600. The disease ran an uncomplicated, typical course, and thirteen blood examinations proved negative.

Case III.—A. Z., aged ten years, admitted May 23, 1899. Present history of seven days' standing, beginning with abdominal pain, fever, and diarrhœa. At present bowels are costive. On admission, temperature was 104° F.; pulse, 130; respirations, 30. Spleen enlarged to percussion; abdomen soft and negative. May 24, diazo reaction present. June 17, hemorrhage from bowels; temperature curve atypical. August 2, discharged cured.

As a reason for the persistent absence of the reaction in these cases, an explanation might have been offered which has been given in similar cases in which the Widal reaction has remained repeatedly negative, and that is, that the Widal reaction had disappeared before the patient had arrived at the hospital. But it will be seen that, at least so far as the clinical histories of these cases can be trusted, the patients came in too early for such an occurrence to have been possible. It must also be noted that in a number of instances the day on which the reaction first became positive belonged to the period of convalescence or relapse. An instance of the latter will be given later.

It is interesting in this connection to review the statements made by Thursfield[6] in his recent thorough article, with which we are hardly in accord. He states that he found the reaction present in the first examination in forty out of forty-two cases; and concludes that negative reactions are trustworthy evidence that the disease is not typhoid fever; and also states that "a negative reaction later than the tenth day of the illness was strong proof, but not convincing evidence, of the absence of typhoid fever. From our experience we would rather say that a negative reaction in any fever case means very little as regards the existence or absence of typhoid fever.

Although in many instances we have had to wait a long time to obtain a positive reaction in cases in which it was hardly needed to confirm the clinical diagnosis, we have had the good fortune, generally, to find the reaction occur early in cases in which it was essential for establishing the diagnosis. Among such cases were those of so-called cerebral typhoids and pneumonic typhoids, and cases in which a complication was really the first symptom of the disease. To illustrate this, we cite the following cases as examples:

Case I.—F. M., aged five years, admitted September 11, 1900. For twenty days he has complained of headache and pain in the abdomen; he has a dry cough and fever at night; no chills, no epistaxis; for the last four days diarrhœa. On admission, lips were dry, tongue coated, no roseola present. Temperature, 104.6° F.; pulse, 140; respirations, 30. The examination of the chest revealed a dull note at the apices, with increased breathing and some crepitant râles in the left axilla, and diminished breathing in the right axilla. Heart and liver negative; spleen not increased in size to percussion, nor palpable. Abdomen slightly distended, very rigid.

The general appearance of this case was that of a bronchopneumonia; but as it has been our custom to suspect the existence of typhoid fever in all cases occurring during the summer and autumn months which gave pulmonary or meningeal symptoms, the blood was examined the day after admission, and the reaction found to be present in dilution of one to fifty. On September 15, the spleen was palpable. The patient was apathetic. From that time on the general condition improved, and the patient was discharged, October 30, cured.

Case II.—R. F., aged four years, admitted April 14, 1901. Previous history, had pneumonia two years ago. Present history, has been ill eight days with fever; no vomiting, no epistaxis, bowels costive, urine normal. Temperature, 102.6° F.; pulse, 160; respirations, 34. Tongue, moist and coated. Examination of the chest revealed a few moist râles over both sides of the chest in front. There was dulness at the left apex extending to the spine of the scapula with increased breathing. Liver negative, spleen not enlarged to percussion, nor palpable; abdomen negative; no roseola present. April 17, a profuse macular eruption appeared all over the body, and the child was isolated on a suspicion of scarlet fever. The following day the Widal reaction was positive in a dilution of one to fifty. April 19, the typical typhoid roseola appeared on the back, and the spleen became palpable just below the free border of the ribs. On the 24th, temperature was normal. Discharged on the 27th, cured.

In this case the child was isolated as a suspected case of scarlet fever; and the Widal reaction became positive before the cardinal signs of typhoid fever appeared. Dr. Koplik was inclined to regard this case as an "exanthematous" typhoid.*

Case III.—R. C., four years of age, admitted July 28, 1901. Present history of two days' duration beginning with cough, headache, rise of temperature; no vomiting, no chill, no epistaxis; bowels regular. On admission, temperature was 104.6° F.; pulse, 150; respirations, 32. Tongue moist and coated; no roseola present. Lungs, dull note at both apices; near the angle of the left scapula, breathing is tubular. Spleen not palpable; abdomen negative. July 29, the leucocyte count was 9,600. Widal reaction negative. July 31, another reaction positive, dilution one to fifty. The child's condition gradually became worse. August 3, Widal reaction became positive, one to one hundred. Signs of pneumonia increasing. Spleen not evidently enlarged. August 4, Widal reaction was positive in dilution 1 to 350, and the same day the child died. There was no autopsy.

This case throughout its entire course had the appearance of a case of lobar pneumonia. As the Widal reaction was negative on the third day of the disease, and became positive later, even up to dilution of 1 to 350, the case must be considered one of typhoid fever.

An investigation of the family history made after the death of the child still further confirmed the diagnosis. Three other children took sick with typhoid fever soon after our case was sent to the hospital, one of which died. A man living on the floor above, and a boy on the floor below, also contracted the disease at the same time. The former was treated in our own hospital for typhoid fever, and died. The

*Such cases have been described by Angeli and Aron (Abstracts in *Gaz. hebdom. de méd.*, 1900.)

clinical history was straightforward and the Widal reaction present. (No autopsy.)

CASE IV.—M. A., aged nine years, admitted July 11, 1901. Present history of two weeks' duration, beginning with headache, fever, no vomiting, no epistaxis, no chill, no discharge from the ear. Five days after the onset the physician diagnosed pneumonia. The child then improved, but for the past five days has been semi-conscious, and the temperature has reached 106° F. On admission the temperature was 104° F.; pulse, 126; respiration, 38. The status was as follows: General condition fair, child unconscious, discharge from the right ear. Tongue dry. Two maculo-papular spots on abdomen, rigidity of neck, reflexes increased. Ankle clonus present. Marked Kernig's phenomenon present. Pupils are equal, and react to light. There is clonic spasm of the muscles of mastication. Lungs, some dulness at the left apex with increased voice and breathing; respiration, slow and irregular; heart, negative. Liver, fully two and a half fingers below free border of ribs. Spleen, large and palpable.

On first sight, this case would have been considered one of meningitis; but previous experience with the meningeal type of typhoid fever, and the presence of an enlarged spleen, prompted us to make a probable diagnosis of typhoid fever with meningeal symptoms. The blood was examined the day after admission; the reaction found positive, one to fifty. A lumbar puncture was later made. The fluid was clear, containing a trace of albumin, but was negative on culture.

At the time of writing, the child is in the hospital just recovering from a second relapse of the disease.

CASE V.—The following case was published by Dr. A. A. Berg, in the MEDICAL RECORD, June, 1901. J. H., aged seven years, admitted to the surgical service of Dr. Gerster on August 18, 1900, with a diagnosis of purulent peritonitis following appendicitis. There was no previous history. Present history was of one week's duration, beginning with headache and general lassitude. No abdominal pain, bowels irregular, no fever. The patient had not been confined to bed. Early on the day of admission he complained of violent cramps in right iliac fossa and vomiting. On admission, temperature was 103° F.; pulse, 136; respiration, 26. Lungs and heart negative, abdomen distended and very rigid, spleen and liver negative. Operation on the same day by Dr. Berg; appendix found normal. Small perforation found low down in the ileum. After the perforation was sutured, the case progressed favorably, and the temperature reached normal the tenth day after operation.

The blood in this case was carefully examined for the Widal reaction, and it was not until September 8 that the reaction became positive. It served to confirm the suspected diagnosis of typhoid-fever perforation. This case serves also as an example of the type of cases in which the Widal reaction does not become positive until after convalescence is established.

Conclusions.—I.—The main facts concerning the Widal reaction in children are the same as those that hold true for adults.

II.—In eighty-four cases of typhoid fever in children, ranging from one and a half to fourteen years of age, eighty-one cases gave a positive result.

III.—In 115 cases that were fevers other than typhoid, the positive reaction was never obtained.

IV.—The reaction did not occur later in children than in adults, as is claimed by some writers, but on the other hand, somewhat earlier. However, we would not lay too much stress on this point.

V.—The Widal test is of greater importance in children than in adults, owing to the frequent atypical character of the disease in the former, and the greater frequency of cases resembling pneumonia and meningitis.

VI.—As pointed out by Morse, the reaction will be of service in establishing the frequency of typhoid fever in children.

I wish to take this opportunity to thank Dr. Koplik for the use of the material and encouragement, and Dr. Libman for his kind aid in the course of the work.

Nephrolithiasis and Spinal Disease.—These two affections, according to H. Schlesinger, may have an etiological relationship, and he has collected a number of cases in which renal calculi appeared in conjunction with some cord lesion. The spinal trouble usually preceded the kidney history by several months, and the percentage of simultaneous occurrence of the two is too high to be explicable on the ground of mere coincidence. Renal calculi have frequently been found in cases of traumatism to the cord, and in syringomyelia, less often in spinal tumor. Once they accompanied acute encephalomyelitis. The symptoms may not appear till months or years after the beginning of the spinal affection. The calculi are most often phosphatic, but may also be uratic. Cystopyelitis does not necessarily occur, but is usually present with phosphatic concretions. The spinal trouble may have a direct or an indirect influence on the formation of the renal stones (perhaps, particularly in the case of uratic calculi; a predisposition is necessary.—*Wiener klinische Rundschau.*

Examination of the Blood Corpuscles in Typhoid Fever.—The conclusions of W. A. Winter are as follows: 1. The number of the red blood corpuscles gradually diminishes as the fever progresses, but with the establishment of convalescence, regeneration sets in. 2. The number of leucocytes is diminished throughout the course of the fever. This rule does not hold good in all cases, but is so constant that if, in a given case of a non-eruptive fever, the number of leucocytes is normal or subnormal, it would be a strong point in favor of the diagnosis of enteric fever. 3. There is a progressive diminution in the percentage of the polymorphonuclear cells, which continues into the stage of early convalescence. 4. The percentage of the large mononuclear leucocytes is increased throughout the whole course of the fever, and continues into the stage of early convalescence. 5. The percentage of the lymphocytes is increased throughout the fever, the increase being most marked in the stage of convalescence. 6. While the fever lasts, the percentage of the eosinophile cells is subnormal, but with the establishment of convalescence, it again reaches and may even pass the normal level.—*Dublin Journal of Medical Science.*

Clinical Department.

A CASE OF ACTINOMYCOSIS.*

By LEONARD WEBER, M.D.,
NEW YORK.

Though more than forty cases of actinomycosis in man have been published since Bollinger, in 1876, drew attention to the occurrence of this fungous disease in cattle, and James Israel and Ponfick, in 1878, described the first cases seen by them in human beings, I do not hesitate to communicate my case which is confirmatory as to the general symptoms and usual course of the disease reported by previous observers, but appeared to be entirely unaffected by the administration of iodide of potassium as recommended by some. The patient had taken a great deal of the iodide for old specific disease before he was infected by actinomyeosis, so it was not a preventive; and he took a regular course of it for the established disease before and after operation, but also without lasting benefit. The fungus may invade the region of the neck and jaw—it does so quite frequently—or the lungs and chestwall, abdominal parietes and viscera, skin and subcutaneous tissues, or very rarely the meninges and brain. In the last case I know of, published by Professor Nikitin of St. Petersburg, in the *Deutsche medicinische Wochenschrift*, 1900, No. 38, the morbid progress began in the respiratory organs of a woman, thirty-eight years old, thence spread to the integuments and lymphatics, and ended in the brain, having lasted about two years. My case started in the jaw and face of a man in March, 1895, and ended with the symptoms of pneumonia in July, 1897.

S. B. H., æt. fifty-two, single, bookkeeper, with whom I have been acquainted for twenty-seven years, had been sound and vigorous in early youth, and remained so until he had the misfortune to contract syphilis in 1879. The disease, though never really dangerous, was rebellious and obstinate in its manifestations, so that it was not until 1890 that he finally became free from all specific symptoms and remained so for some years. January 26, 1895, he presented himself again, complaining of a small, hard, tender, and painful swelling on the outer side of the right seventh rib. It was due to syphilitic periosteitis, yielded quickly to iodide of potassium, and had entirely disappeared by February 24, when the patient had taken two ounces of the drug.

At the beginning of March, he felt some pain and noticed a sore and inflamed-looking area at the outer side of the last two molars of the right lower jaw. One of the teeth was removed, the other treated by a dentist, and the gums were attended to, but pain and soreness continued more or less. On March 20, he noticed a distinct swelling of the part of the face extending from the angle of the right lower jaw upward to the temporal region. Mastication became now somewhat difficult, the swelling, which was never hot or particularly tender, increased, and when he presented himself on March 26, I had no difficulty in discovering deep-seated fluctuation in the same. I suspected a broken-down gumma, on account of the patient's previous history, but sent him for further examination and eventual operation to Dr. Lange's hospital. Some of the fluid was aspirated and a specimen of it placed under the microscope, when actinomyces fungi with their characteristic forms were seen to be present in large numbers.

As to the history of the infection it may be stated that the patient had the habit of picking off and chewing ears of rye or wheat when walking about in the country in the summer. Through a tender spot of the gums of his lower jaw the fungus had found an entrance and had spread into muscle and bone quite extensively at the time the patient presented himself. A thorough and painstaking operation was performed by Dr. Lange, and no diseased part was left behind, so far as could be seen, and no untoward event interrupted the slow granulation and filling up of the rather large cavity, the healing of it being completed by the end of June. A narrow fistula about one and a half inches in depth remained, discharging a little thin pus from time to time. Mr. H. returned to me September 30, 1895, and said that he felt no ache or pain; in fact, he looked better and healthier than at any time before.

On March 8, 1896, the retracted cicatrix and surrounding parts were somewhat tender and there was a slight discharge from the fistula, but nothing of the old disease could be discovered by probing and microscopical examination of the wound-secretion. I ordered iodide of potassium, gr. xv. t. i. d. By April 7, he had taken about two ounces of the drug, and there was no more swelling or tenderness, but just a drop or two of secretion from the fistula.

On February 6, 1897, there were no symptoms and the fistula was in *status quo*.

On July 5, 1897, the patient was taken with the symptoms of pneumonia of the right lung, and died July 10. I did not happen to be in town when he was taken ill, but learned from one of his friends that for two weeks prior to his last illness he had some bronchial catarrh, with peculiar grayish-brown expectoration, not accompanied by fever. The pneumonia was said to be of asthenic character without high temperature, but with a very weak pulse. No autopsy was made.

From this and other records of this infectious disease, it would appear that the duration averages from eighteen months to two years, that no reliance should be placed on the iodide of potassium in trying to cure it, but a thorough operation be done, wherever possible, as soon as the diagnosis has been made. To be sure, a doubt remains whether the inflammation of the right lung, of which my patient died, was caused by actinomycosis of that organ, but it is at least probable that this was the case.

25 West Forty-sixth Street.

*Read before the German Medical Society of New York, March, 1900

A CASE OF MULTIPLE UNILATERAL CRANIAL NERVE PARALYSIS.

By PHILIP KING BROWN, M.D.,
SAN FRANCISCO, CAL.

Ah Lung, a native of China, fifty-eight years old, a coal miner by occupation for some years past, presents the following history: His health up to one year ago was perfect. He has not had syphilis, does not drink or smoke tobacco, but has smoked opium a little. While working in a shaft in a coal mine a year ago, he began to have pain in the right eye, which was much aggravated by exposure to cold. He worked with a pick and shovel and noticed that the draft in the shaft struck the right side of his face. His face felt cold on that side all the time, the pain soon became constant day and night, and seemed to him to be deep in the eye. A doctor gave him something to drop in the eye, and he states that since then he has been unable to see. He has not observed anything else about the head, except a progressing deafness in the right ear, and a loss of feeling in the skin on the right side of the head. He does not know

when these symptoms were first noted, but they developed very soon after the eye trouble. At present, he complains of a pain deep in the eye and shooting up across the forehead, and he keeps his hand constantly over the eye. He says the pain is worse now than at any time since the onset of the trouble a year ago. During the summer he was quite free from pain.

A physical examination of the patient showed nothing abnormal about his thoracic and abdominal organs; there was no eruption on his body, nor were there any enlarged glands or scars on the penis. Several large scars on the body were explained to have resulted from injury. There were several small patches of alopecia on the head, but these seemed to be due also to injury. The right side of the face and particularly the forehead were of a much deeper brownish color than the left side. The pigmentation was blotchy, but covered the face on the right side almost entirely. Perspiration was certainly more profuse on the right side. Smell was practically gone on the right side, as was also vision. There was an opacity of the anterior chamber which prevented the nerve being examined, but there was not even perception of light on that side. Marked conjunctivitis of the right eye, ptosis of the right lid, and internal rotation of the eye were noted. No conjunctival reflex was present, but there was marked arcus in both eyes. There was complete sensory and motor paralysis of the right half of the face and anterior part of the scalp, and also complete deafness in the right ear. The sense of taste in the right anterior part of the tongue was gone entirely and diminished in the right posterior part.

There were no abnormalities of the left cranial nerves particularly noted in regard to the nose and eye symptoms. The tendon reflexes throughout the body were equal and normal, and there were no other anæsthetic areas found. The Justus and tuberculin tests were negative. No rise of temperature occurred during the three days I was able to keep the patient in the hospital. The blood examination was negative. Iodide of potassium was given in full doses for several weeks without effect, and the patient finally disappeared unaffected by treatment. Phenacetin, even in 10 gr. doses, failed to relieve the pain.

In this case, paralysis was complete in the first eight cranial nerves with the possible exception of the fourth. By way of explanation I can only suggest a diffuse bone sarcoma, such as has been found in a number of the small series of these cases already reported.

HALLUCINATION OF SNAKES.

By W. MOSER, M.D.,
BROOKLYN, N. Y.
PHYSICIAN TO THE GERMAN HOSPITAL.

It is well known that certain hallucinations are intimately associated with a morbid mental state, as for instance the visual hallucination of "seeing snakes" in delirium tremens. A recent observation has convinced me that this symptom is not peculiar to alcoholic delirium, but may occur in a form of insanity independent of alcoholism.

The affection or symptom was noted in two members of the same family suggesting its hereditary nature. Both saw snakes either on the floor, or "in heaven," as the girl remarked. The symptom was first noted in the boy and girl about the age of puberty. In addition to this symptom they were also impulsive, so that when annoyed they might prove dangerous, and for this reason need watching. The parents were not addicted to drink. The prognosis, which must cautiously be given in cases of mental alienation, is apparently better than in that condition in which the individual believes his abdomen to be inhabited by the reptile. This form is associated with gastric disturbance and sensory delusions of pain, and with auditory hallucinations arising from the false conception (Bechterew).

It is worthy of remark that in so-called alcoholic insanity this peculiar hallucination does not occur, or to be more conservative, it is certainly not a part of its clinical history. It is not my object to describe a new disease or to class everything with hysteria, but this is described with the hope that it may be of some practical value in diagnosis and prognosis, and stimulate therapeutic research.

A PERSONAL EXPERIENCE WITH MUSHROOM POISONING.

By E. A. BLOUNT M.D.,
OAK PARK, ILL.

One day last month the Man of Science of our house came home with a fine specimen of large white mushroom which he took to the library and identified as "horse mushroom." As this was pronounced edible by the authority consulted, a few from the fine patch were collected and prepared for dinner. While collecting them in the vacant lot at 2 P.M., the Man of Science ate a small piece of one, raw, as a trial dose. At 5 P.M., feeling entirely well, he tried another piece, this time taking a piece as large as the little finger, likewise raw. At 6 P.M. he felt generally ill, and could not eat a mouthful of supper. Half an hour later he began to have profuse, but painless, watery bowel movements. He attributed his ill-feeling to drugs used by the dentist that afternoon, as the taste of them was continuous; but I was strongly suspicious that mushrooms were at the bottom of the trouble.

Observing the feeble effect of the amount taken, I resolved to test the matter. Forbidding the family to partake of the fungi, I took two small portions, each as large as a pea, and swallowed the juice of two other portions of like size, though the pulp I could not bring myself to swallow. The first taste was pleasant, but the after-taste created an immediate loathing. This was at 6 P.M. Immediately they caused symptoms of discomfort. There was a warm, heavy sensation, similar to that first experienced upon taking acetanilid; also a slight spasm of the pharyngeal muscles, with difficulty and disinclination in swallowing.

Immediate loss of appetite was resisted, and the meal was finished. The next hour was spent with a sense of indescribable discomfort in the stomach, and at 7 P.M. I resolved to end it by gastric lavage. Before this process could be begun, however, I had vomited twice with great force, and after several unsuccessful attempts, the idea of washing the stomach was abandoned. During the next two hours, vomiting continued at intervals of five to ten minutes, and toward nine o'clock vigorous medication was commenced. By this time there had been several watery movements of the bowels, and these continued throughout the next day.

The violence of the paroxysms of vomiting I have only seen equaled in one case of tropical malaria. I felt as though each one must end with a convulsion, but it never came to that. The burning pain in the stomach was intense and indescribable. Feelings of lassitude and exhaustion intervened between the paroxysms, but the rest was spoiled by the haunting horror of the next attack, which began with dread of its being the last.

At 9 P.M., or about that time, a professional friend began to administer vigorous hypodermic medica-

tion, which, together with ¼ gr. of cocaine by the mouth, produced immediate relief. Only two paroxysms of vomiting followed, at considerable intervals. By 11 I had sunk into quiet slumber.

The drugs administered were: Cocaine, per os, gr. ½; and strychnine, gr. 1/30; atropine, gr. 100, and morphine sulphate, gr. ¼, hypodermatically. The pulse was weak and rapid, and perspiration free at this time. Slight exertions were extremely exhausting.

The Man of Science vomited three times during the evening, and his diarrhœa continued through the night. He did not lie down at all, and felt as usual the next day.

The striking point in this report to me is the extreme smallness of the dose which I took, and the violent symptoms produced, as well as the mildness of the symptoms of the Man of Science, from a much larger quantity of mushroom.

The mushrooms were identified by C. V. Chesnut of the Department of Agriculture as lepiota morgani, or green-spored lepiota.

CASE OF TORSION OF THE SPERMATIC CORD.

BY A. B. ATHERTON, M.D.
FREDERICTON, N. B., CANADA

SINCE torsion of the spermatic cord is rarely met with, and as it is only in recent years that the attention of the profession has been called to its occurrence, I have thought it might be well to place on record a case in which I have recently operated.

On October 14 last, I was called by telephone to see, in consultation with Dr. Camp, a boy, aged fourteen years, who was supposed to be suffering from a strangulated hernia. After a drive of some seventeen miles, I arrived on the scene at 7 A.M. From Dr. Camp I got the following history of the case: The boy had been as well as usual until the morning before, when he felt some pain in a swelling in the left groin. He went about, however, as usual, without making much complaint till the evening. Dr. Camp was sent for in the night, and made an attempt to reduce the supposed hernia under chloroform. After coming out of the anæsthesia the boy vomited for the first time. The only cause assigned for the appearance of the swelling was the fact that the day preceding it he had engaged in a jumping contest.

On examination I found the abdomen quite flat and neither tender nor painful on palpation. All the complaint was of a swelling in the left groin. The pain did not seem very severe. The boy's countenance and pulse were good. The lump in the left groin extended from the top of the testicle, being continuous with it, up to a point nearly two inches above the external inguinal ring. It was about one and one-half inches in diameter, and felt somewhat softish and very tender to the touch. It was dull on percussion and gave no impulse on coughing. The left testicle was not so low in the scrotum as the right. At the operation, chloroform was given by Dr. Camp, who also assisted otherwise. An oblique incision one and one-half inches long was made, and a thin, dark sac was soon reached, which, on being opened, gave exit to some serous fluid, and then a dark bluish congested epidermis popped out. On drawing upon this, there followed the upper part of the congested epididymis, with the cord from above and the testicle from below. The cord was twisted twice on itself, and it and the epididymis were engorged and thrombosed, like the neck and base of a twisted ovarian tumor. The testicle, on incision, presented a dark maroon surface. The cord was ligatured in three sections with catgut, and cut away, the swollen epididymis and the testicle being also removed. Part of the tunica vaginalis was likewise taken away, the edges of the remainder being sutured with catgut. The skin edges were brought together with interrupted wire sutures, and an antiseptic dressing was applied.

The after-treatment was carried out entirely by Dr. Camp, who reported healing in a few days without suppuration.

Poisoning from Anilin Oil Used in the Ear.—Homer Dupuy reports the case of a girl of seventeen years with diffused inflammation in the right auditory canal following a mastoid attack. A mixture of cocaine 15 grs. in 1 ounce of the oil was ordered, 15 drops to be instilled in the meatus hourly. After about five instillations, the patient became drowsy, suddenly cried out, lost consciousness, became blue in the face, had a cold and clammy skin with a profuse perspiration. The ear was washed out, atropine and strychnine were given with aromatic spirit of ammonia, hot bottles were applied, and brandy was given. The patient was out of danger in twenty-four hours, but remained weak for some days. Dupuy states that in spite of this untoward occurrence he has used the combination given in the ear without any bad symptoms. He adds that in the last eight months the solution composed of cocaine 20 grs., absolute alcohol and anilin oil 30 minims each, has been used on a hundred cases for tympanotomy in acute otitis media, and yet not a single instance of drug poisoning, even in the milder form referred to, has come to his notice. From this rather extensive experience, he believes that he is fully justified in using the mixture for operative work on the drum and contiguous parts; on the other hand, we cannot with impunity place so toxic and so readily absorbed an agent as anilin in the hands of patients for purposes of frequent instillation. Tympanotomy once performed, the canal should be thoroughly syringed, thus removing the danger of further absorption.—*The Laryngoscope.*

Recurrent Peritonsillar Abscess.—According to H. J. Hartz, this condition is due to abnormal anatomical relationship of the plica triangularis, supratonsillar fossa, and tonsils. Fibrous adhesions between these organs predispose to lacunar abscess, which, burrowing into cellular tissue investing the tonsils, cause peritonsillar abscess. Adhesions and an enlarged upper portion of the tonsil obstruct the outlet of the supratonsillar fossa, causing suppuration in this space, which extends into the pharyngomaxillary space, producing a chronic abscess which ultimately discharges through a fistula in the soft palate region. The tonsil region, like the vermiform appendix, is subject to abscess formation through inflammatory adhesions. The pent-up secretion becomes a culture medium for pathogenic germs. Surgical measures are the indications for treatment. Excision of the upper portion of the tonsil obstructing the supratonsillar fossa and the removal of the plica triangularis are necessary. Adhesions must be broken up or removed by punch forceps.—*The Laryngoscope.*

Poison of Tapeworm.—Messineo and Calamida (*Rif. Med.*, July 17, 1901) believe that the effects of tapeworm are not due so much to mechanical reasons as to some toxic substance in a secretion by the tænia itself. They found that by injections and inoculations of extract of tapeworm, constant and characteristic symptoms were produced—for example, tremor, depression, paresis of posterior extremity, somnolence, etc. These symptoms were more marked in the case of non-stored extracts than in those where the extracts had been kept at temperature of 40° to 45° F. Control extracts showed that the results were not due to the injection of proteid substances merely, but especially related to the tapeworm. All the species tried gave the same result.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, November 23, 1901.

SOME RECENT STATISTICS OF CARCINOMA OF THE TONGUE.

So far, in spite of considerable effort, bacteriology has not succeeded in incriminating any microorganism as the causative agent of carcinoma, and consequently surgery remains our most important resource in the treatment of malignant disease. It is, therefore, a satisfactory fact that recent statistics show that, with modern technique, the period of immunity from recurrence after radical operation is lengthening, and the percentage of apparent cures is reaching a more and more satisfactory figure. Some figures in *Beiträge zur klinischen Chirurgie*, Band XXXI, Heft 2, in an article by Roediger of Czerny's clinic, show what has been done in one prominent surgical institution with a form of disease which is justly much dreaded.

From 1888 to 1900, thirty cases of carcinoma of the tongue were operated upon in this clinic, and the results given in Roediger's paper are worth analyzing. Nothing new in regard to etiology seems to have been elicited, and the usual factors are mentioned, such as carious teeth, smoking, and hereditary influences; but it is interesting to note that the first manifestation of the disease was a nodule in fourteen instances, and an ulcer in ten. The comparatively favorable fact is mentioned that metastases are rare, and that the lymphatic glands in the neighborhood are involved early by continuity of tissue.

The most interesting and noteworthy part of the paper is that devoted to the subject of treatment, which was invariably some form of operation. The methods chosen were both simple, through the mouth, with scissors and cautery, and extensive, with resection of the jaw and other such radical measures; and it is shown, without doubt, by the figures in this series, that the latter plans of treatment offer greater prospect of immunity from secondary trouble than any of the less radical methods. No patient died from inhalation pneumonia, but four died very soon after the operation from shock and collapse—a very favorable showing. The subsequent history of the other cases which could be traced presents many points of interest, and some of encouragement. In regard to eight, no information was obtainable, so they must be removed from consideration; in five cases early secondary operation, on account of recurrence, was required; in seven instances, death is known to have occurred from recurrent disease; and in seven others, good health and freedom from recurrence persisted through periods varying from eleven months to three and one-half years. The remaining cases are known to have died, but the circumstances were not discoverable. Thus, seven cases out of thirty remained free from recurrence after operation for periods so long that they may be put down as cures; and these figures represent an encouraging percentage, especially when we remember that there may have been one or two patients among the eight who were lost sight of, that remained free from disease. A very important fact is that among the seven patients who remained free from any sign of disease for the periods mentioned there were two, out of the nine, who had been subjected to the less extensive operations through the mouth, and five, out of the sixteen, upon whom severe operative work, involving such procedures as resection of the jaw, was done. This represents a very decided percentage in favor of radical operation, an *a fortiori* of early diagnosis. Other operators, among whom may be mentioned Wolfler, have reported corresponding results.

This experience, with one variety of malignant disease, only confirms what is readily deducible from every such collection of statistics, and that is, that, in order to hope reasonably for improvement in the figures of the period of immunity, the diagnosis must be made early, and, above all, the operation must be radical. The percentage of "cures" in this series is comparatively very favorable, and gives promise of still better results when the conditions of early diagnosis and radical operation are more often united in the same patient. A good word might be added for the thermocautery in operations upon the tongue. Its good possibilities do not seem to be generally appreciated.

ADAMI ON KOCH.

WHEN, last summer, Professor Koch announced his belief in the probable non-identity of bovine and human tuberculosis, the MEDICAL RECORD showed that the discovery—if discovery it was—belonged in no sense to Koch, for he was neither the first to make it, nor the first to proclaim it, having been anticipated by several American workers. In the current issue of the *Canadian Journal of Medicine and Surgery*, Professor J. George Adami writes at length on the same subject, and shows that Koch must have known that the investigations made by himself and Schütz were simply a repetition of those of Frothingham, Theobald Smith, and Dinwiddie. Adami, in August, 1899, read a paper on this subject before the Canadian Medical Association, in which he reviewed the work that had been done, and discussed the arguments *pro* and *con* at considerable length. It is hardly conceivable that Koch failed to see this paper, for the German Consul at Montreal asked for and received copies of it for transmission to his government. It is a serious fact that it was just about this time that Koch and Schütz began their inoculation experiments at Berlin.

In discussing this charge of plagiarism, to which Koch has so often laid himself open, Adami says:

"It is very possible, and it happens not infrequently, that an active worker and writer occasionally, and by accident, fails to credit his fellow-workers; but when this failure to acknowledge the observations of others is frequently repeated, no excuse can be asked or can be accepted. Either the individual who commits the crime is absolutely callous, and has callously determined to aggrandize himself at the expense of others, or he suffers from a form of disease—from

megalomania, by which we mean that such an individual becomes so full of his subject, and of himself, that he regards every idea and every fact as his own, whether the idea has previously been enunciated, or is the natural and independent development of his own line of work and thought, or has been, in the first place, obtained from the work and the writings of others. We are inclined to think that the second is the more probable explanation in the case of Professor Koch. When, for example, he announced the discovery of tuberculin, he had not a word to say with regard to the observations of the other workers who had previously investigated the action of the products of growth of the tubercle bacillus, among whom I may mention Crookshank of London and, if I mistake not, Büchner of Munich. He took all the credit to himself. When next he described (and described imperfectly) his method of preparation of tuberculin, no credit was given to Roux and Nocard for the discovery that the tubercle bacilli would grow in media to which glycerin had been added, glycerinated broth being the medium from which he prepared the tuberculin. When, later, he gave his observations upon the chemical nature of tuberculin, not a word was said about the previous careful observations of Hunter and of others, who had before him reached practically identical results, and, indeed, had made fuller researches. Only recently, taking up the subject of malaria, he has had the hardihood to take to himself all the credit for the discovery of the important part played by mosquitos in the propagation of this disease, and has refrained from saying a word of due praise concerning the prior observations of Ross, and Italian and yet earlier American workers. These facts are well known to those conversant with bacteriological literature, but such is Professor Koch's power and influence in Germany that younger men dare not disclose these matters in the public press, for fear lest their careers should be injured, while his colleagues of professorial rank say nothing about the matter, fearing lest it should be thought that their motive was one of mere jealousy. It is left to those of other nationalities to bring forward these facts, unpleasant as they are."

It does certainly seem to be "up to" Professor Koch to disprove, if he can, the repeated charges that most, if not all, of his discoveries of late years have really been only inventions.

THE IMPROVEMENT OF TOWNS AND CITIES.

There is no evading the fact that one of the most conspicuous features of the present age is the rush of people from the country to towns. By the census recently taken, throughout the whole civilized world, it has been conclusively shown that the tendency to prefer an urban to a rural life is decided and widespread, and in no countries has this disposition been more strikingly evinced than by the inhabitants of the United States and Germany.

Into the reasons for this wholesale desertion of the country, this is no place to enter, nor is there need for discussion as to whether this movement is for good or evil. Suffice it to say that it is so, the reason must be accepted, and it only remains for physicians, sanitarians, and philanthropists to endeavor to render the conditions of life in cities and towns as morally and physically healthy as possible.

The first necessity of any area crowded with human beings is that it should be above suspicion from the standpoint of hygiene, that is, drainage should be effective, water supply plentiful and pure, and, in short, that all sanitary arrangements should be conceived and carried out with the sole view of safeguarding the lives and health of the population.

For many years now, in the most enlightened countries of the earth, men of light and learning have been slowly but surely arriving at the truth that the municipal problem is the one deserving of the closest attention, and for a nation chiefly dwelling in cities, the necessity is obvious that these cities must be made healthy places of abode. If this be not done, the race will rapidly deteriorate physically, and be unable to compete on equal terms with the inhabitants of countries who live under a more intelligent sanitary rule. Thus earnest and sensible social reformers have been bending their energies toward converting large centers of population into comparatively salubrious places of residence.

Mr. C. M. Robinson has lately published a book in this country, on the improvement of cities and towns, in which he sets forth a mass of statistics and details concerning the subject. The book in question, while it does not neglect to insist upon the paramount importance of hygiene, gives much space to advocating the cultivation of the beautiful in the construction and arrangement of cities.

The writer aptly points out that in most countries of the European Continent rigid laws are enforced to prevent contractors and builders from offending too grossly against the æsthetic sense. Paris, perhaps the most artistic city of the world, was rendered so by the efforts of Napoleon III, ably seconded by Baron Hausmann. Modern Berlin has been to a great extent rebuilt and greatly beautified by the Kaiser. London, though its buildings are, as a rule, incongruous to a degree, within recent years has been refurbished and brought somewhat into line with the ideas of modern progress through the public-spirited action of the civic authorities, while some of the other large cities of Great Britain are models of how such places should be managed. Many of the cities of this country are on a par with, or even superior to their European rivals, and it is evident that throughout the world, the dominating note in municipal reform is to make the conditions of city life desirable from a physical, moral, and æsthetic point of view.

The most difficult problem with which to deal in cities and towns is how to repress noise. In American cities this feature is even more prevalent than in Europe, and constitutes the most serious objection to living among the "madding crowd." It should, however, be clearly understood that many of the numerous and varied noises which shatter the nerves and shorten the lives of the inhabitants of towns are altogether unnecessary, and could be promptly ended if a strong stand were made against their continuance.

With the abolition of needless noises, and with the various improvements which have been suggested put into force, city life will have been robbed of many of its terrors, and may in time become the ideal place of residence. There is, nevertheless, much to be done to bring this Elysian dream to pass.

Children and Tuberculous Milk.

Dr. George F. Still of London has always contended that tuberculous milk was an infrequent cause of infection in the young, and claims that the commonest channel of infection with tuberculosis in childhood is through the lung.

Dr. Boivard, Jr., of New York read a paper before the Section on Pediatrics at the New York Academy of Medicine relating to this question, and has likewise concluded that milk from tuberculous cows is responsible for but few cases of tuberculosis among children. In support of his contention, Dr. Boivard quoted statistics of the New York Foundling Hospital, which has regularly in its care about 2,000 children. In 250 autopsies performed at that institution upon the bodies of children who had died of tuberculosis, it was found that but five cases, or 2 per cent., of definitely primary intestinal infection occurred among them.

Nocard's conclusions are practically identical, as are those of many other authorities.

Nevertheless, if it be allowed that these distinguished men are right, it should by no means follow that efforts to banish tuberculosis from cattle should not be pursued as vigorously as ever.

That milk from a cow infected with tuberculosis is not as wholesome as that drawn from a healthy animal is obvious enough even to the non-scientific individual.

Football in America.

The football season is now at its height, and the results of the matches between the different college teams are eagerly followed by an army of partisans and other devotees of the game.

The reports of the condition of the players after a particularly brisk match between two noted elevens, as given by the press, would be amusing, were it not sad. When one reads that such and such a man is in hospital from the effects of injuries received in a former game, but that the coach trusts that he will be sufficiently recovered to take part in the match of the season; that another man has had his shoulder dislocated; that several more are suffering from sprained ankles and slight hurts of that description, and, finally, that out of the whole number some two thirds are rendered temporarily *hors de combat*, the fact is irresistibly borne upon one's mind that this game of football has decidedly its serious, not to say brutal, aspects.

Of course, it is quite right that youths should not be coddled, and should take a part in manly games; but the increasing vehemence with which football is played, and the manner in which the contestants are frequently maimed, have given rise to grave doubts as to whether the so-called game of football, as now conducted in this country, is not somewhat too strenuous.

The Plague.

The news comes from various quarters of the world that where present the plague shows but small signs of abating, and that the disease is constantly cropping up in fresh localities. In India, the Eastern pest rages with as much virulence as when it first occurred on a large scale, while the surmise is shrewdly made, from the meager accounts which are allowed to leak out by the military censors in South Africa, that there are a large number of cases in that country. Glasgow has had a recrudescence of the epidemic, Liverpool has been invaded, and ominous rumors have been recently current that for the first time for many years the disease has gained an entrance into London.

The plague situation in San Francisco is at the present time somewhat of a mystery, but there can be no doubt that several Chinese in the Pacific Coast capital are plague-stricken. Civilized countries in which the laws of sanitation are properly observed, need be in no fear of an extended epidemic; but at the same time, the strictest precautionary measures should be enforced to prevent the disease from gaining a foothold, and promptly to stamp it out if, perchance, such an event should happen.

Tetanus from Antitoxin.

In Milan, Italy, some few months ago, many persons died from tetanus, the poison having been introduced into their systems by the agency of impure anti-diphtheritic serum. This unfortunate accident has been reduplicated recently at St. Louis, where twenty individuals developed tetanus with fatal results after antitoxin treatment for diphtheria. The infection with the germs of lockjaw has been traced to contaminated antitoxin, procured from a horse, whose blood was tainted with the bacilli of tetanus.

Such occurrences are most unfortunate, as they tend to give a handle to the animadversions of the opponents of methods of this nature, and create in the public mind an unwarranted prejudice against prophylactic measures which have been proved of the utmost value in preventing disease and insuring the health of the whole community.

It is to be hoped that the lesson taught by the unhappy incident in St. Louis will be taken to heart by boards of health everywhere, and that extraordinary precautions will be taken to provide against a similar catastrophe.

Spurious Grippe in New York.

Reports have appeared from time to time in the New York lay journals recently that grippe was prevalent in the city. It appears, however, that these accounts were false, or rather founded upon insufficient premises.

Numerous persons have been and many are yet troubled with colds, which simulate grippe in many particulars, but, nevertheless, are not of specific character. These affections are usually sudden in their attacks, but fail to present the distinctive features of infection by the microbe of epidemic influenza. There are lacking the high fever, the racking pains, the lassitude, and the many other symptoms which distinguish that insidious disease from all others. The malady from which a large number of the inhabitants of New York is at present suffering is probably what used to be known as an ordinary autumnal cold, and for which the changeable weather at this season of the year is responsible. The specific disease so aptly termed the grippe is happily absent from New York and neighborhood.

The Water Supply of New York City.

The question of a pure water supply intimately concerns every inhabitant of New York, and is perhaps of greater vital importance than any of the numerous matters which will confront the new administration when it comes into power. Analysis has shown that the water supplied to the metropolitan city contains, even when at its worst, no germs especially injurious to health, and as regards quantity, there can be no grounds for adverse criticism.

Nevertheless, although satisfactory from a sanitary standpoint, the fact cannot be denied that at times the water supply of New York offends both the sense of smell and of taste. The remedy for this lies in filtration, as has been pointed out in the Medical Record many times. The outlay to improve the water supply by these means would undoubtedly be large, but after all it would be to the ultimate benefit of the population at large.

News of the Week.

An Epidemic of Tetanus.—Seven or more children have died in Camden and one in Atlantic City, N. J., from tetanus following vaccination. The disease in each instance appeared two or three weeks after the vaccination, but the mode of infection has not been discovered. Two themes have been offered to account for the outbreak; one, that the vaccine was pure, and that the wounds became infected, after the maturation of the virides, through the deposit of tetanus bacilli from the dust of the streets; it is urged that the interval of time which elapsed between the vaccination and the appearance of the first symptoms of tetanus, was too long to warrant the assumption that the virus was impure. The other theory is that the virus contained in sealed tubes afforded a good culture medium for the anaerobic tetanus bacilli with which it had in some way been infected. As the source of most of the virus is well known or can be easily ascertained, it ought to be a not impossible task to determine whether or not it is pure or contaminated with the germs of tetanus. The occurrence of two epidemics of tetanus, one following the injection of diphtheria antitoxin, and the other seemingly caused by vaccination, is most unfortunate in that it will furnish ammunition to the half-informed or fanatical opponents of these two life-saving measures. The cause of the St. Louis outbreak has been determined, and its moral is obvious. The origin of the Camden epidemic must, in the interest of public health, be determined with the least possible delay.

Insanity Among Teachers.—A communication to the *New York Times* notes that, according to the statistics of the State Hospital for the Insane at Elgin contained in the last biennial report, one person in every sixty admitted during the last two years had been a school teacher. In that period 660 persons were received at the asylum, ten of them being women teachers. At the Kankakee institution, 1,061 persons were admitted during the last two years. Of these eighty-three were accredited to the "professions," no division being made for teachers. Prof. Zimmer of Berlin said in a report of investigations he had made in Austria, Switzerland, Russia, and Germany, that in every eighty-five woman insane patients one was a school teacher.

Montefiore Home.—Dr. Alfred Wiener has been appointed adjunct neurologist to the Montefiore Home.

The Plague.—The Health Committee of Liverpool declared on November 14 that the city was free from the bubonic plague. A river boatman employed on a tug working on the River Lee was admitted on the same day into a London hospital for treatment for what was suspected to be the plague. The Peninsular and Oriental Steamship Company's steamship *Peninsula*, from Bombay to London, arrived at Marseilles November 18 with bubonic plague aboard. One patient died at sea. The health authorities of St. Petersburg and Odessa have reported the occurrence of one death from the disease in each of these cities. In Rio de Janeiro several new cases are reported almost daily. The Canadian quarantine authorities now require the surgeon on every ship arriving at any port in the Dominion to take the temperature of every one of the passengers and crew within twenty-four hours prior to the arrival of the vessel. By this means the surgeon will be enabled to examine closely every person on board, and the quarantine officers will be aided in detecting any case of illness of a possibly suspicious nature. In the annual report of the San Francisco Board of Health, Dr. J. M. Williamson advocates the complete destruction of Chinatown which, he says, "cannot be rendered sanitary except by total obliteration. It should be depopulated, its buildings levelled by fire, and its tunnels and cellars laid bare. Its occupants should be colonized on some distant portion of the peninsula, where every violation of sanitary laws could at once be detected. In this and no other way will there be safety from the invasion and propagation of Oriental diseases. The day has passed," he says, "when a progressive city like San Francisco should feel compelled to tolerate in its midst a foreign community perpetuated in filth for the curiosity of tourists, the cupidity of lawyers, and the adoration of artists."

Cholera is epidemic in the Island of Java, over a hundred cases being reported daily at Surabaya, a town of about 150,000 inhabitants.

Cablegrams received in Washington state that bubonic plague has broken out in Odessa. Reports from Manila state that the plague epidemic there, and also at Hong-Kong and Amoy, is a thing of the past. No fresh cases of plague have occurred in Glasgow since November 1st.

The New York Obstetrical Society.—At the meeting of the New York Obstetrical Society held November 12, Drs. A. Jacobi and Paul F. Mundé were elected Honorary Fellows.

University of Pennsylvania.—Dr. Charles K. Mills has been elected Professor of the Diseases of the Nervous System; Dr. Charles W. Burr, Professor of Diseases of the Mind, and Dr. Wm. G. Spiller, Assistant Professor of the Diseases of the Nervous System.

The sum of $500,000 has been pledged by friends of the University for the improvement of Franklin Field, the erection of a gymnasium, and a general increase in athletic facilities.

Dr. George Woodward has made a gift of $20,000 for the establishment of the Woodward Fellowship in Physiological Chemistry.

Investigations carried out during the summer under the auspices of the Rockefeller Institute of Preventive Medicine have disclosed the presence of the specific bacillus of disentery in the disease prevailing in the United States, thus demonstrating the fact that the dysenteries of tropical and temperate climates are identical.

Burial of Soldiers.—Instructions have recently been issued by the War Department to insure uniform sanitary methods for the burial of the remains of soldiers dying outside the limits of the United States, and to facilitate their subsequent disinterment for removal to this country for final burial. For this purpose, wooden coffins are used, having holes bored in the bottom to facilitate the escape of fluids. The remains are clad for burial in ordinary clothing, and the space remaining in the coffin is filled with freshly burned lime. As it is desirable that the soft parts shall disintegrate as rapidly as possible, the use of hermetically sealed metallic coffins is discouraged. The remains of soldiers who have died of contagious disease are wrapped in sheets wet with corrosive sublimate solution or formalin and buried without coffins in graves packed with lime, the bodies being covered to a depth of six inches with the same material. On disinterment for return to the United States, the remains, usually left undisturbed for a year after burial, are at once wrapped in sheets wet with a disinfectant solution. The remains of each soldier are then placed in a metallic casket with a movable top which is tightly clamped down against a rubber gasket, previously thickly coated with white lead. An air-tight joint is thus formed. The casket is

then inclosed in a stout box for shipment, being packed around with sawdust to prevent injury to, or movement of, the casket. During the first fiscal year, the remains of 1,825 officers, soldiers, sailors, and civilians have in this way been returned from the West Indies and the Pacific Islands, and given honorable burial in the United States.

Philadelphia County Medical Society.—At a stated meeting held November 14 Dr. J. Dutton Steele read a paper entitled "Gastroptosis and Gastric Motor Insufficiency." Both of these conditions, which are often associated, may be unattended with any change in the chemism of the stomach, and the treatment is principally mechanical, by means of supporters and the like, and in part medicinal; the principal remedy being strychnine, preferably in the form of nux vomica in ascending doses. The general condition and general measures should not be neglected. Dr. H. C. Wood, Jr., read a paper entitled "Quinine Rashes," reporting an illustrative case in which an exanthem appeared after the ingestion of two drachms of compound tincture of cinchona, which contains but a small amount of quinine. Drs. Wm. M. Welch and Jay F. Schamberg read a paper entitled "The Characteristics of Genuine Vaccination; Some Statistics of the Prevalent Smallpox Epidemic." It was again shown that the disease, as well as the fatal cases, occurred only in small proportion in those who had been vaccinated, and in these with relatively lesser frequency in accordance with the character of the scar.

A New Hospital for St. John's Guild.—At the thirty-fifth annual meeting of this society, held last week, Mr. William Sherer, President of the guild, said that the reports of the standing committees showed an increase in membership of 23½ per cent. and a balance of $31,839, as compared to the deficit of last year. He outlined the plan of the convalescent hospital, which the society intends building on its grounds at New Dorp, Staten Island. The present Seaside Hospital is a frame building, and has proved inadequate owing to the growing work of the society. Sufficient funds to defray the cost of building the new plant have not yet been obtained, but the trustees are confident of the success of the plan when its need becomes generally known. It includes a much enlarged and improved hospital, nurses' and physicians' dormitories, and quarters for the male and female help employed by the society.

Hudson River State Hospital, Poughkeepsie, N.Y.—Dr. J. Elvin Courtney has resigned the position of Chief of Staff of Hudson River State Hospital, Poughkeepsie, N. Y., and removed to Denver, Col.

Addition to Hospital.—The Roberts Memorial Annex to St. Timothy's Hospital, Roxborough, Philadelphia, built at a cost of $85,000, was formally opened and dedicated on November 16. The building is of red brick and steel, and has a frontage of forty-nine feet on Ridge Avenue and one hundred and twelve feet on Rector Street. It is four stories high, with a basement, and is fitted throughout with the latest approved appliances. The basement contains an *X*-ray room, a museum, storeroom, and a boiler-room, while on the first floor are situated a store-room, two bath-rooms, a kitchen, surgical, medical, and receiving wards, a dressing-room, and a quiet room for patients fatally injured or hopelessly ill. The second floor is like the first, with the addition of three private rooms. On the third floor are eight private rooms, drying, bath and store rooms, and on the fourth floor, two commodious bedrooms and an attic. On the Ridge Avenue front is a double sun parlor, 17x40 feet. The building will be heated by the indirect steam system, with forced draught, from boilers situated off from the Annex. All of the rooms and corridors will be flushed automatically with pure air four times an hour.

Assistant Professor of Hygiene.—Captain E. L. Munson, Assistant Surgeon U. S. A. has recently been appointed Assistant Professor of Military Hygiene in the Army Medical School in Washington, D. C.

Fourteenth International Medical Congress.—Circulars and announcements relating to this Congress, which is to meet in Madrid, April 23-30, 1903, have already been issued by the Secretary, Dr. Angel Fernandez-Caro, and the President, Dr. Julian Calleja. Every effort is being made to secure a large attendance at the Congress as the sending out of circulars eighteen month before the date set for the meeting would imply.

Pathological Society of Philadelphia.—At a stated meeting held November 12 Dr. M. B. Hartzell made a "Report of a Case of Fibroma Molluscum," exhibiting most extensive tumor formation. Drs. Jos. McFarland and Geo. M. Boyd presented a specimen of "Hypernephroma of the Kidney." Dr. Roland G. Curtin exhibited the "Largest Recorded Aneurysm of the Heart," and also a specimen of "Anæmic Necrosis of the Wall of the Left Ventricle." Dr. David L. Edsall reported the results of a "Study of the Urine in a Case of Family Periodic Paralysis." In this case he found a marked reduction in the amount of creatinin excreted prior to and during the attack, with a rise approaching the normal in the sequence of attack. He infers that there must be some derangement of metabolism responsible for these changes, and that they are at the bottom of the muscular disability. Dr. D. J. McCarthy presented a communication entitled "Experimental Lead Encephalopathy with Microscopic Lesions in the Brain." The histologic sections exhibited cellular and vascular proliferation in the subcortical layer of the brain. Dr. W. T. Longcope exhibited a stained preparation and cultures upon various media of the "Streptococcus Mucosus." Dr. David Riesman exhibited a specimen of "Albuminous Expectoration" from a case in which the evacuation of fluid from the pleural cavity was followed by the expectoration in a short time of a considerable amount of viscid fluid of gelatinous consistency, which yielded reactions almost identical with those of the aspirated fluid. In this instance, it was thought the phenomenon was the result of puncture of the lung, though in other instances it has been thought to be due to an acute œdema of the lung.

The Rudolph Virchow Fund.—This fund was started ten years ago to celebrate the seventieth birthday of Professor Virchow, by establishing scholarships and by encouraging special medical and biological studies. Subscriptions to this addition to the fund were asked from physicians in all parts of the world, and committees were formed in every country to take charge of the local collections. It was decided some time ago to celebrate the great scientist's eightieth birthday by an increase of this fund, and subscriptions for this object are looked for from Virchow's admirers in every country. The scholarships, when they are founded, are to be awarded to students of any nationality, who stand first in a competitive examination which will be held once in a given period in Berlin. The number of scholarships and the details in regard to the examinations have not yet been decided upon. Subscriptions from Ameri-

cans should be sent to Dr. A. Jacobi, 19 East Forty-seventh Street, New York. The American committee in charge of the subscriptions consists of Drs. C. A. L. Reed of Cincinnati, H. P. Bowditch of Boston, W. K. Welch of Baltimore, and R. F. Weir and A. Jacobi of New York City.

The Society of the Jewish Hospital of Brooklyn has recently been incorporated at Albany. The object of the society is to erect and conduct a hospital in which medical and surgical care will be given to the sick without distinction as to creed or nationality.

The Harvard Veterinary School.—Several students, who had not yet completed their course in veterinary medicine when the Harvard Trustees decided to close that department, have been transferred to the University of Pennsylvania Veterinary School, Harvard paying for their tuition there. When the students complete their course at the University of Pennsylvania, they will receive a diploma which will be accepted as the equal of that given by Harvard, and the connection of Harvard University with the teaching of veterinary medicine will then cease. Prof. Lyman, who was dean of the Harvard School, accepting the place for life, has been pensioned.

The Pasteur Monument in Paris.—It is stated in *Nature* that a difficulty has arisen, concerning the site on which the new Pasteur statue in Paris shall be erected. The use of a space in the Square Médicis in the Quartier Latin has been granted, but this spot is being tunneled for a railway, and it is feared, in consequence, that the statue may be too weighty for it. Other places, such as the Place du Panthéon, the Place de la Sorbonne, and the entrance of the Avenue de l'Observatoire, are under consideration.

Measles in Alaska.—It is reported from Nome that the natives of western Alaska are rapidly disappearing as the result of disease. At least one-third of the native population at Cape Nome, Prince of Wales, Nome, Port Clarence, St. Michaels, Kuskokwim, Unalaska, Pribyloff Islands, Nunivaki Island, and St. Lawrence Island, and those along the Yukon River have suffered from the effects of an epidemic, which at first was thought to be smallpox, but upon investigation proved to be measles.

Investigation of a "Vita Physician."—The Coroner of Philadelphia recently summoned Victor B. Hall, who designates himself a "Vita Physician," to explain by what authority he issued a death certificate in the case of a woman who died of what was termed "tubercular deposit." The man stated that he was the founder and chief instructor of the Order of Vital Friends, which had been organized in Canada seventeen years ago, and had a Canadian charter. The Philadelphia branch was organized twelve years, and includes eighty-two families in its membership. In addition to a secretary and treasurer, there is an officer known as "Vital Dietist." The avowed purpose of the society is to do away entirely with the use of drugs in the treatment of diseases, and to substitute the life-giving properties of pure food and air. The annual membership fee is $5, which insures attendance in case of sickness. The three cardinal principles of the treatment are said to be "adaptation, application, and operation."

Philadelphia Teachers Must Be Vaccinated.—A teacher in the Philadelphia Girls' High School recently applied to the courts for an injunction against the Board of Education, which suspended her for refusing to comply with its order to procure a certificate of successful vaccination within the last five years or else submit to an inoculation. The court denied the injunction, and now the teacher must submit to vaccination or resign her charge.

The Diploma Mill in Jersey City.—The President of the "Central University of Medicine and Science" in Jersey City, John W. Norton-Smith, who appends to his name most of the degrees conferred for a consideration by his "university," was arrested a few days ago on a charge of attempting to obtain money under false pretenses. He had been distributing letters throughout the country, offering a diploma and a degree of M.D., Ph.D., or LL.D. for the moderate sum of $15. The same man was arrested for the same offense last summer.

A Rare Case.—A man died suddenly in the street, one day last week, of a profuse hæmoptysis. In his pocket was found a rough draft of a letter to a physician whose name did not appear, which read as follows: "I trust you have not thought me a 'dead beat.' I have had a hard time getting along, and when you asked me for some money on account of my bill, I was ashamed to tell you I was 'broke.' Rather than do that, I stopped your treatment, for I could not ask further lenience about the bill. The lack of treatment has put me back in my old condition, but now, thank God! I can ask you to take my case again. I inclose $10 on account, for I have now 'got on my feet.' I am sure you will cure me, though I am very weak for lack of medical attention. I thank you for your many kindnesses."

The St. Louis Tetanus Cases.—The report of the bacteriologists appointed to investigate the recent deaths in St. Louis from tetanus, following the use of diphtheria antitoxin proposed by the City Board of Health, says that the serum given out in the first three weeks of October was impure. "From the facts stated," the report runs, "we are forced to conclude that the diphtheria antitoxin prepared by the City Health Department had been issued before it was possible to have obtained results from the absolutely necessary tests. Had these tests been performed, the results upon animals would have been such that the serum would not have been dispensed, and the cases of tetanus forming the basis of this report could not have resulted."

Heredity and Cancer.—The German National Committee for the study of cancer has announced its conclusion that cancer is rarely, if ever, hereditary, but it has not formulated any opinion as to the pathogenesis of the disease. It has been announced that the German emperor has requested Professor Ehrlich to devote his whole time and energies to the study of cancer. At the same time, the Professor will have the advantage of a magnificently appointed chemical and bacteriological institute, while a competent bacteriologist and pathologist has been appointed as his assistant.

Philadelphia Pediatric Society.—At a stated meeting held November 12, Dr. James K. Young exhibited a patient on whom "Astragalectomy for Inveterate Clubfoot" had been performed, with a good functional result. Dr. John H. Jopson reported "Two Cases of Operation for Impacted Calculus in the Urethra." In one, extravasation of urine occurred and death ensued, in spite of operation, while in the other recovery took place. Dr. F. A. Packard presented a communication entitled "Methods of Vaccination."

The method preferred consists in thorough asepsis, and the use of a special scarifier carried in absolute alcohol, and of glycerinated lymph followed by the application of a protective shield of some sort, which should, however, not be permitted to remain in place for too long a time. Dr. Morris J. Lewis read a paper entitled "Remarks on What Constitutes a Successful Vaccination." It was pointed out that the typical lesion of primary vaccination is not, as a rule, produced by secondary vaccination. The latter was successful in nearly 85 per cent. of cases, in many of which vaccination had been practised successfully only a few years ago. Dr. J. Frank Wallis exhibited a number of wax models illustrating the lesions of smallpox and of vaccinia at different stages and of varying type. Dr. Arthur Van Harlingen read a paper entitled "Remarks on Vaccination in Relation to Skin Diseases and Eruptions following Vaccination."

Obituary Notes.—Dr. JARVIS S. WIGHT died at his home in Brooklyn on November 17. He was born in Centreville, Allegany County, N. Y., in 1834, and after being graduated from Tufts College in 1861, studied medicine at the College of Physicians and Surgeons, in this city, and later at the Long Island College Hospital, where he received his degree in 1864. During the Civil War he served as assistant surgeon in a volunteer regiment, and at the close of the war became surgeon to the Long Island College Hospital Dispensary, and was successively lecturer on skin diseases, professor of materia medica, of the principles and practices of surgery, and professor of operative and clinical surgery—a position which he held up to the time of his death. For many years he was the registrar of the college. He was consulting surgeon at St. Mary's Hospital and at the Eastern District Hospital.

Dr. ISAAC R. SMALL died at his home in Brooklyn on November 13 at the age of 77 years. He was a graduate of the College of Physicians in this city and practised medicine for nearly forty years in Greenpoint. He served one term as coroner in the Eastern District of Brooklyn.

Dr. CALVIN EDWARDS HULL, a retired physician of Brooklyn, died at his summer home in Black Rock, Conn., on November 13, at the age of 89 years.

Dr. GEORGE H. MARMION died at his home in Washington, on November 13, of apoplexy. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1866. He was a son of Dr. Nicholas Marmion, who was a very well-known physician of Harper's Ferry, and a brother of Drs. W. V. Marmion of Washington and Robert A. Marmion of the Navy.

Dr. STUART ELDRIDGE, Acting Assistant Surgeon of the Marine Hospital Service, who was on duty in the office of the United States Consul-General at Yokohama, Japan, died November 18. Dr. Eldridge was a native of New York, but had resided in Japan for many years. At the time of his appointment in the Marine Hospital Service, he was a member of the Imperial Board of Health, of the Tokio Health Office, and sanitary adviser to the Japanese Government. He was an honorary member of the Medical Society of the State of New York and the Bellevue Hospital Alumni Association.

Dr. WILLIAM FISHER NORRIS of Philadelphia died at his home in that city November 18, aged sixty-three years. Death was due to pneumonia. Dr. Norris was graduated from the Medical Department of the University of Pennsylvania in 1861. He was appointed an Assistant Surgeon in the Union Army and served throughout the Civil War, being in charge of the Douglas Hospital at Washington in 1864. He was a former President of the American Ophthalmology Society, and was for thirty years attending surgeon of the Wills Eye Hospital. He was Professor of Ophthalmology at the University of Pennsylvania at the time of his death. Dr. Norris was a prolific writer and a recognized authority on diseases of the eye.

Dr. DAVID C. REYNOLDS died at Philadelphia of apoplexy on November 12 at the age of seventy-one years. He was graduated from the Medical Department of the University of Pennsylvania in the year 1852, and engaged in the practice of medicine at McVeytown, subsequently removing to Lockhaven, and finally to Philadelphia.

Dr. SAMUEL ASHHURST of Philadelphia died in London, Eng., on November 13, of an attack of bronchitis complicating fatty heart at the age of sixty-one years. He was graduated from the Medical Department of the University of Pennsylvania in 1861.

Obituary.

ALBERT LEARY GIHON, M.D.,

U. S. NAVY.

Dr. Albert Leary Gihon, Medical Director, U. S. Navy, retired, died in this city, of cerebral apoplexy, on Sunday, November 17, at the age of 68 years. He was born in Philadelphia, September 28, 1833, and was graduated from the Philadelphia College of Medicine and Surgery in 1853. He was professor of chemistry and toxicology in the same college for two years, when he entered the navy as assistant surgeon in 1855. He was serving on the sloop-of-war *Portsmouth*, and took part in the engagements which resulted in the capture of the Barrier forts at Canton in November, 1856. He served in various ships until 1860, when he was assigned to the Brooklyn Naval Hospital for a year. When the brig *Perry* captured the Confederate privateer *Savannah*, he was on board the former vessel. He was on the *St. Louis* in its hunt after the privateers *Alabama*, *Florida*, and *Georgia*, and in 1865 was assigned to do duty at the Portsmouth yard as senior medical officer. He was on board the *Idaho* at Nagasaki, when she was wrecked in the big typhoon of September 21, 1869. For his work in the Portuguese colony at Dilly, on the island of Timor, and on the Portuguese men-of-war *Principe Dom Carlos* and *Sa da Bandeira* he received from the King of Portugal the decoration of Knight of the Military Order of Christ. Dr. Gihon designed the model hospital ship which was exhibited at the Centennial Exposition of 1876, and the ambulance cot approved and used by the navy was designed by him. He was made Surgeon in 1861, Medical Inspector in 1872, and became Medical Director in 1879, and later served at Washington, Mare Island, Brooklyn, and New York. In 1893, he was transferred to the post at Washington in charge of the medical headquarters. He was then senior medical officer of the navy, and was placed on the retired list in 1895, having reached the age limit of sixty-two years.

Dr. Gihon was an accomplished writer, and was the author of many works on medicine and travel. He was a man of companionable disposition and lovable nature, and surrounded himself with warm friends wherever he was stationed in his forty years of naval service. He was a frequent attendant at medical meetings, where he was sent as official representative of the navy. His earnest but futile appeals in behalf of the Rush monument were for many years a feature of the successive meetings of the American Medical Association.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ELECTIONS—HEALTH OF THE KING—SMALLPOX—PLAGUE—THE CONTROVERSY—CLINICAL SOCIETY'S EXHIBITS—HÆMATURIA IN CHILDHOOD.

London, November 11, 1901.

This is the month of elections. The provincial municipalities are to-day engaged in them, and in town the Lord Mayor's show approaches.

The General Medical Council election is also exciting a languid interest, the formal notices have been issued that nominations must be delivered by the 21st instant, and the candidates are busy stating their claims in speeches and circulars. The retiring members for England are Dr. Glover and Mr. G. Brown. Both offer themselves for re-election, and three other candidates have also declared themselves.

For Scotland, Dr. Bruce is to be opposed by two candidates so far as at present known.

The health of the King has been made the subject of many newspaper paragraphs—some of them of a very disquieting nature, but there seems no foundation for the sinister rumors. The doctors, who could not fail to know, say that His Majesty's health is excellent, and certainly the activity he displays supports their assertion.

Smallpox has increased all through the week. From ten new cases with which Saturday closed last week, this week began with nineteen on Sunday, which was followed by twenty-five, twenty-eight, twenty-nine, and twenty-one on successive days. Last night there were 279 cases under treatment in the isolation hospitals.

The increase has thoroughly alarmed a considerable section of the public, and there is quite a rush on vaccination, showing how hollow is the outcry of the faddists. This has caused a run on lymph. The local Government Board has ordered 250 calves within a fortnight, and fifty-three were inoculated last week. But this is not all the demand, and private institutions for providing us with lymph are having unusual prosperity.

The occurrence of plague at Liverpool has been much talked of. From time to time during the last two years a case has been imported, which is not surprising considering that ships put in at the port from every part of the world. During the week, two children died of what is shown to be plague by bacteriological evidence. Three other cases are isolated in hospital. It is suggested that the infection came from Glasgow in a patient who lately died from what was thought to be influenza. But the period of incubation does not support this, and other evidence fails. However, the authorities are wide awake, all contacts of the known and suspected cases are being watched, and Dr. Hope, the M. O. H., is satisfied that the public need not fear an extension of the disease.

The Registrar-General's returns for the quarter ending September 30 have just been issued. The rate of mortality in the urban districts was 18.2 per thousand; in the rural parts, 14.2. In London the rate was 17.1. In the thirty-two next largest towns it averaged 20.5.

Do you remember the Imlach controversy? It is almost like ancient history, for it was thought to be closed some fifteen years ago, but it is cropping up again. All that time ago, Dr. Imlach was treating pelvic hæmatocele in the manner which is now held to be the best by a great number of gynecologists. But he seems to have been in advance of his contemporaries and to have had to bear the penalty of opposition to an extreme degree. The opponents of his views took the matter to the Liverpool Medical Institution, which appointed a committee to consider his proceedings. That committee's report was in effect a censure, but did not close the controversy, though it is said to have ruined Dr. Imlach. Pamphlets have been issued by his defenders and opponents in which many side issues are discussed—one of which is whether the Liverpool Medical Institution had any *locus standi* in such a matter and consequently whether the committee was not throughout acting *ultra vires*. A far more important point would seem to be whether any such committee of surgeons or physicians was at that date competent to pronounce a decisive verdict on new gynecological operations. Be that as it may, the inquiry was made by the committee and Dr. Imlach censured, though it is now said this was on the ground that he did not sufficiently explain to his patients the effects of his operations. It is difficult to believe that this was the sole motive of the censure, which had the effect of depriving Dr. Imlach of his hospital appointment. Seeing that leading gynecologists are now continually performing the operations he practised, his friends ask the Liverpool Institution to delete from their records their proceedings in the matter. They decline to do so on various grounds—such as that after so long a time re-inquiry is impracticable and deletion would be censuring the committee. Arbitration has been proposed, but this also the Institution declines. We have certainly not heard the last of the question. Already many are comparing the proceedings of the Institution with those of the War Office, which has just caused indignation throughout the country and weakened the Government by dismissing General Buller after an equally star-chamber sort of inquiry.

Dr. Imlach does not seem to be making a very unreasonable demand in asking for arbitration in the light of the advance of gynecology. The *British Medical Journal* opposes this, and counsels not to ask the Institution to abase itself. Yet in 1886 the *Journal* spoke out very vigorously against the assumption of the Institution.

The cases exhibited at the Clinical Society's last meeting included one of right-sided hemiparesis with atrophy of left optic disc, the nature of which seemed very obscure. It was suggested that the patient might have had thrombosis in the neighborhood of the left motor tract with recto-bulbar neuritis of left optic nerve, or perhaps the condition might be due to early disseminated sclerosis.

Another person—scarcely to be termed a patient—shown had incomplete development of both clavicles. On each side the sternal ends with the attachments of the sterno-mastoids can be felt; there seems some attempt at development toward the acromial ends. The intervening space seems occupied by fibrous structure, perhaps representing the costo-coracoid membrane. The defect does not interfere with the occupation of the subject of it, who is a clerk, aged twenty; nor has it hindered him from playing cricket, and he can bowl as well as others. He can do what his companions cannot, viz., brings his shoulders so near to the median line that the tips of the deltoids touch.

Two cases involving joints may be compared. One, an old man with osteo-arthritis; his ligamentum patellæ has been ruptured and previous to that the bone had been twice fractured; it can now be felt some distance up the thigh. There is a large fluid swelling in front of the knee-joint which has been aspirated three times and pressure applied. This has not reduced the fluid. The man gets about with comparative ease, and perhaps the fluid in the joint cavity may help rather than hinder.

The other arthropathy is in a young woman of twenty-six, who has suffered from bronchitis for eighteen months. The sputum from the first was offensive, but became more and more copious twelve months ago, and the ankles began to swell. The wrists, knees, and fingers became involved subsequently, and muscular debility was well marked. The offensive sputum has lost its factor and is less in quantity.

Mr. Bowlby remarked on the case as relating to those resembling osteo-arthritis and which have been traced to sepsis. Some other cases of arthritic symptoms set up by sepsis were mentioned by members.

Hæmaturia in childhood has given most practitioners a degree of anxiety on account of its numerous causes and the alarm it excites in parents, who are apt to demand an immediate answer to their questions as to its origin and prognosis. The subject was brought before the Harveian Society on October 17 by Mr. Campbell Williams in a paper remarkable for its completeness, which, however, necessitated a degree of conciseness that made it very difficult to follow.

In some cases, Mr. Williams encountered the difficulty of deciding, if not on the source of the hemorrhage, at least on its cause, even with the aid of sound, microscope, skiagraph, and cystoscope, if it can be introduced. By watching the patient pass urine into a glass beaker, he had sometimes been able to determine whether the blood came from the urethra, bladder, or kidneys. The character of the blood or clots may give a clue, but not always. The smoky or porter tint of the textbooks characterizes a renal origin, but if very copious such a hemorrhage may simulate one of vesical or urethral source. Hæmaturia is often surgical, but may be medical. Thus it occurs in children's complaints. Rickets, scurvy, hæmophilia, anæmia, tuberculosis, purpura, Raynaud's disease, may present the symptom, which also occurs in renal infarction, pneumonia, nephritis, typhus, variola, malaria, diphtheria, and scarlet fever. Sometimes it is due to parasites, and sometimes to drugs.

Passing all these by with a mere mention, Mr. Williams proceeded to consider cases within the domain of surgery, and to state his experience and views regarding them. The only fault to be found with this paper is that it is almost too condensed.

OUR PARIS LETTER.

(From Our Special Correspondent.)

THE FIGHT IN FRANCE AGAINST CONSUMPTION—GAUTIER'S METHOD OF GIVING CACODYLATE OF SODA—THE SULTAN'S HEALTH—PINARD ON THE TREATMENT OF ECLAMPSIA—NEW REMEDIES IN DIABETES (LÉPINE OF LYONS)—FREQUENCY OF KOPLIK'S SIGN—ARTIFICIAL LARYNX—GUINARD'S MODIFICATION OF TUFFIER'S TECHNIQUE.

PARIS, November 5, 1901.

EFFORTS are being made in France to fight consumption by different prophylactic measures. In the army, for instance, the Minister of War has ordered the use of spittoons in the rooms occupied by the soldiers, as well as in the passages in the barracks. These spittoons are to be made out of zinc, and their dimensions are certainly generous enough. They are to be a foot long, and half a foot high. The Minister of Public Works has sent a circular to the railway companies insisting on the selection already carried out in the choice of the employees, on the necessity of giving outdoor work to those who are tuberculous, and of sending such as may need it to the sanatoria already in existence. Consumption is very rife among school teachers, and at a recent meeting held by the different mutual help societies of school teachers, at the Sorbonne, it was decided that it would be well to found a sanatorium of 110 beds, for which an annual endowment fund of 40,000 francs will be furnished by the different societies.

Cacodylate of soda is talked of as much as usual. Dr. Armand Gautier has been indicating recently the symptoms which indicate intolerance, and which are congestion, with general excitation, buzzing in the ears, and vertigo. There would seem to be hardly any counterindications, even fever, diarrhœa and vomiting not seriously interfering with its use. Cardiac insufficiency, however, and hypertrophy of the heart, as well as cirrhosis of the liver, would be conditions that would justify abstaining from using this drug. Professor Gautier recommends using at the same time the following preparations:

Chloride of sodium	6 gm.
Iodide of potassium	
Bromide of potassium	āā 1 gr.
Water	q. s. for 100 c.c.

Take an hour before lunch a dessertspoonful of this preparation.

During the course of the meal, a soupspoonful of the following mixture should be taken in half a tumblerful of water:

Phosphate of calcium	30 gm.
Hydrochloric acid	10 gtt.
Chloride of sodium	15 gr.
Ammonium magnesian phosphate	10 gm.
Ammonium fluoride	15 gr.
Crystallized citric acid	12 gr.
Sugar	100 gm.
Water	1000 gm.

Several works have been published recently on the use of cacodylate of soda. In Dr. Jalaquier's work the following results are noted: rapid increase in the number of blood globules, better nutrition of the skin and mucous membranes, amelioration of the digestive functions. Dr. Jalaquier advises using not more than 5 centigrams a day in a 5-per-cent. solution.

The internate of the hospitals of Paris will celebrate next year its one hundredth anniversary, and researches have been made to find out what became of the first of the thirteen internes named in 1802. His name was Alin, and he was a friend of the poet Lamartine, who described the latter part of his life and his death in his work called "Raphael." Dr. Alin occupied himself about works of charity, and died in poverty.

According to one of the French papers, the *Rappel*, the Sultan has been suffering during the last three months from a recurrence of nephritis. A specialist from Munich has been called, and has declared that an operation was necessary. It would also seem that the Pope's health is far from good. He can now hardly write, experiencing difficulty in writing the three letters of his name. He has also fainting spells, which become more and more frequent.

The recent discussion at the Congress of Obstetrics as to the best treatment of eclampsia shows how much the opinions of various French accoucheurs are at variance on this subject. Hirigoyen of Bordeaux posed as the partisan of active measures, insisting as he did upon immediate dilatation and extraction of the child. The latter's life was assured thereby in certain cases. Professor Pinard argued that there was no systematic treatment. Complete statistics should be published, with a large number of cases where the same treatment had been followed out. He was not in favor of venesection or obstetrical operations. The prognosis of this affection depended upon the condition of the liver cells, and when the latter were much altered, death would surely take place. As for the children that would be obtained by obstetrical operations, they were apt to die soon after, or to prove a source of expense to their family, or to the state.

Dr. Ollive of Nantes remarked that he had so far had the good fortune never to lose a case of eclampsia, and had always noticed distinct improvement after venesection.

Professor Lépine of Lyons has just published in the *Semaine Médicale* an article on the treatment of diabetes. He remarked that it was well to have the quantity of sugar verified not only with the polarimeter, as done usually by druggists, but also with the Fehling test, as maltine sometimes modified the results obtained with the polarimeter. The quantity of urea excreted is also an important factor, especially after the regimen has been changed. If the ratio observed between urea and sugar remain high, then a severe form of diabetes may be predicted.

Gerhardt's reaction is much insisted on by Professor Lépine. It consists in acting upon the urine with a solution of perchloride of iron. If the urine becomes dark red, the presence of diacetic acid is demonstrated, provided no drug is being administered which can produce this change. According to Lépine, this is much more important than the acetone reaction. If, after treatment, this test is still found, the prognosis is well-nigh fatal. Professor Lépine thought it well to use a mixed diet, so as to avoid the irritating action on the kidneys. To suppress the diacetic acid, carbo-hydrates are of some value, but they increase the quantity of sugar. Schultzen has recommended glycerin, and Schwarz of Prague has just tried gluconic acid with excellent results. The patient, a man twenty-four years old, was twice treated with this preparation, while in a comatose condition and recovered, diacetic acid disappearing from his urine. The third time, however, there was no gluconic acid to be had, and the patient died the third day. The dose given was 70 grams of gluconic acid neutralized with bicarbonate of soda and administered in half a liter of water. A certain amount of bicarbonate of soda was also given by the mouth and rectum.

A symptom in measles, called Koplik's sign, has been recently investigated by several specialists in children's diseases. This consists in the appearance on the inner surface of the cheeks and on the tongue of small red spots, slightly prominent.

Widowitz, a physician of Gratz, has found it in 142 cases out of 158, *i. e.* in 88.6 per cent. of the cases. He has verified its existence ten times in German measles, once in a case of follicular tonsillitis, and once in stridulous laryngitis. Dr. Moizard, one of the physicians at the Enfants Malades Hôpital, has been looking for this sign in measles, and he has recently noticed this symptom without measles taking place afterward.

At a recent meeting of the Academy of Medicine, Professor Le Dentu presented a patient whose larynx had been removed on account of syphilis. An artificial larynx had been put in, consisting of a canula with resonator and furnished with two rubber plates, which were made to vibrate under the influence of the current of air. Speech is possible, it seems, with this apparatus.

At the Congress of Surgery, held on the 21st of October, 1901, a modification of Tuffier's technique in medullar cocainization was proposed by Dr. Guinard of Paris. Dr. Guinard said that most of the accidents, such as cephalalgia, syncope, or pyrexia, were due to the injection of water, and so he began by tapping the patient and drawing off sixty to eighty drops, which were mixed with six or seven drops of a solution containing one centigram of cocaine to two drops of water. This solution is then injected. Dr. Guinard has already performed fifty operations in this manner without any post-operative incidents.

The Mosquito and Disease.—The *Indian Medical Gazette* says the mosquito is going to be made responsible for leprosy also. In a French exchange we read that Dr. Blanchard stated at the Paris Academy of Medicine that leprosy "could be transmitted by mosquitos," and Dr. Chantemesse remarked that "leprosy was caught generally at night." What the latter statement means, or how such could possibly be proved, we are unable to guess; "other vermin," it is said, are the carriers of "Malta fever," relapsing fever, typhus, and perhaps several skin diseases (R. Ross). Such is the new etiology.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 14, 1901.

Two Cases of Chronic Pancreatitis Cured by Cholecystotomy.—J. W. Elliott reports two cases. Chronic pancreatitis is probably often caused by gallstones. These cause a cholangitis which extends into the duct of the pancreas, giving rise to a chronic pancreatitis, which may obstruct the gall duct, resulting in jaundice, when the gallstones may or may not have wholly disappeared from the gall ducts. Cholecystotomy, by draining the gall ducts and the pancreatic ducts, improves their condition, relieves the back pressure on the pancreas, and finally leads to a cure of pancreatitis.

Medicolegal Examination of Blood Stains.—Edward S. Wood gives practical points in connection with the medicolegal examination of blood stains. Preliminary examination consists in observation of the color, the exact form, the position, and the dryness or moisture of the stain. The systematic examination includes three methods—the chemical tests, the optical method, and the microscopic examination for the detection of the red blood cells. The guaiacum test is chiefly valuable as a preliminary test and as a negative test; for, while other substances give the blue coloration, if no such reaction be obtained, we know that blood is not present. The hæmin test for blood crystals should be used to confirm the guaiacum test. The sodium tungstate test is of great value in cases of washed blood stains, or when a liquid has to be tested for blood. The spectroscopic test requires a considerable volume of blood to deal with. For the new agglutination test it is claimed that it renders it possible to distinguish accurately between human blood and that of other animals.

Journal of the American Medical Association, Nov. 16, 1901.

Suggestions for Lessening the Frequency of Relapses After Treatment of Morphinism.—A. J. Pressey advocates the method of gradual withdrawal. Nearly always when more than ten grains daily have been taken by the patient, he will be comfortable on about one-half the accustomed quantity. After a short continuance with the smaller quantity we again reduce and so on until we get the patient so that he is comfortable on so small a dose as $\frac{1}{120}$ gr., when we try to discontinue it entirely. Static electricity is a valuable adjuvant in treatment.

Total Retroflexion of the Iris.—A. A. Hubbell reports the case of a man of fifty-five years who two weeks before coming under observation had fallen from a wagon and struck the left side of his head and face against the pavement. At the time of his first visit the left eyelids were ecchymotic, the cornea slightly hazy, and the aqueous chamber filled with blood, so that no view of the fundus could be obtained. The subsequent clearing up of the eye showed that the probable train of occurrences had been as follows: A violent concussion of a previously normal eye, followed by aphakia, and disappearance of the iris. The crystalline lens was either dislocated to a point where it could not be found, or else it had become absorbed. The latter supposition is the one accepted. The iris was thrown entirely out of view, and this could only be done by being reflected back against the ciliary body. The mechanism of retroflexion is very obscure, but in this case it evidently consisted, in part, (1) In the destruction of the posterior support of the iris by a laceration of the zonule in a large part of its extent, and thus permitting a sinking backward of the lens whether lacerated or not; (2) In rupturing the pupillary margin of the iris, probably at several points, allowing this membrane to become easily turned back and superimposed over the ciliary body; and (3) After being torn at its pupillary margin, and thrown backward against the ciliary body, the effusion of blood which attended the lacerations necessarily filled the space between the iris and cornea, and thus crowded upon the already reflected iris and held it firmly in its new position till it became so fixed there that it could not replace itself.

Injuries, Feigned and Real, with Their Differentiation and Medicolegal Aspect. Commenting on the difficulty of ascertaining the truth in many cases of the nature suggested by the title, Lambert Ott calls attention to the fact that electrical examination will enable us to determine whether there is actual loss of power in cases of supposed paralysis, that is, determine between real and feigned injuries. More difficult is it to get at the exact facts where there is no visible lesion, and where we must depend on the statements of the patient as to the site and degree of his pain. In regions where persistent pain has been complained of, we should find the following: (1) Primarily an increased electromuscular contractility and later a lessened electromuscular contractility, a result unmilluenced by the patient's will; (2) An increased electrosensibility, a result easily influenced by the patient's will; (3) A glazed, sometimes puffed and bleached, skin over the area of pain; (4) Perverted nutrition of the hair follicles and nails over the region of pain; (5) Possibly some muscular atrophy and flabbiness; (6) Increased skin and muscular reflexes; (7) Unnatural tremor induced by the effort to hold the member absolutely immobile; (8) General lowered nutrition necessarily produced by prolonged suffering; (9) Hyperæsthesia or anæsthesia and variable sensibility to temperature, and (10) The locality of pain bears a close relationship to the distribution of nerves. It must be noted whether the pain and complaint conform to any of the well-known clinical types. If we find the major part of all these signs and symptoms in a region presenting a persistent and prolonged pain; the suffering is real. Ott believes that such cases should come before a jury of physicians instead of laymen.

New York Medical Journal, November 16, 1901.

Social Aspects of Dermatology.—In the tenth Lane Lecture, Malcolm Morris continues his discussion of eczema and speaks also of trade eruptions, psoriasis, mycosis fungoids, pityriasis rubra, malignant affections of the skin, and acanthosis nigricans. He believes that the cause of psoriasis is still unknown. He cannot accept the gouty theory, and no parasite has yet been discovered as having a causative relation to the malady. The neurotic theory derives some support from the association of the disease with arthropathies, which are presumed to be of nervous origin. It may be that in the case of psoriasis, as was suggested in regard to eczema, there are two factors at work—the nervous, which diminishes the resistance of the skin, and the parasitic, which actually gives rise to the disease. The disease is said to be much more common in Europe than in North America.

An X-Ray Stereoscope.—L. A. Weigel says that the correct interpretation of *x*-ray negatives frequently presents considerable difficulty, because all parts of an object lying in different planes are projected into one, and there is practically no way of determining the order of superposition of the various planes and of the distance that separates them. This defect of the ordinary skiagraph is readily overcome by making two stereoscopic negatives, which, when placed in a suitable stereoscope, virtually reconstitute the object in space. Every detail of the negative is seen in its proper place, the surfaces appear in their natural form, and the various planes are correctly separated from each other. The ordinary hand stereoscope is useless for the purpose, because it is too much trouble to obtain prints small enough and much of the fine detail of the original negative is lost in the reduction. The instrument devised by Weigel is figured in his paper, to which we must refer the reader for detailed description. It brings into play the principle that when two plane pictures representing slightly different views of an object are superimposed, they appear to the eye as giving the same relief as the object itself.

Pyopericarditis.—H. O. Collins gives a general description of the disease inclining to regard it, not as a separate malady, but rather as a local manifestation of a pre-existing septic condition in some other part of the body. The primary sepsis may result from mediastinal disease, caries of the ribs, Pott's disease, etc. Cancer or abscess of the lungs, empyema, cancer or abscess of the œsophagus, inflammation of the breasts, and bronchopneumonia should be included in the list of diseases of the chest apt to result in pyopericardium, while myocarditis and abscess of the heart wall are probably to blame for some of the so-called "idiopathic" cases. Those cases which result from external wounds usually fall into the hands of the surgeon in connection with the original injury. Analogous and sometimes perplexing cases are those which result from the perforation of foreign bodies from the œsophagus or the perforation of a small gastric ulcer. The possibility of its being the result of infectious trouble at the navel should not be lost sight of in the new-born. Angina, abscess of the brain, suppurative otitis media, furunculosis, and even vaccination have been known to cause it. Among abdominal troubles, a hepatic abscess may rupture through the diaphragm, or it may result from enteric fever, peritonitis, puerperal fever, abscess of the spleen, appendicitis, or any septic condition of the pelvis. It has also been found in connection with phlegmonous erysipelas, acute osteomyelitis, variola, scarlet fever, typhus, diphtheria, and the malignant form of measles. In those cases where purulent pericarditis complicates gonorrhœal infection, the endocardium is usually first affected, the process being a true metastasis of the gonorrhœal germs. It is generally preceded by the symptoms of gonorrhœal rheumatism, and is more frequently

found in women. In connection with pyæmia, infections of the endocardium and pericardium are responsible for a large proportion of the deaths. Treatment resolves itself into a choice of operative method, either aspiration, simple puncture, incision through an intercostal space, or incision with resection of one or more ribs and through drainage. These methods are described in full by the author.

Medical News, November 16, 1901.

Infantile Pleurisy with Effusion.—W. T. English, in speaking of the difficulties of diagnosing infantile pleurisy, states that one reliable aid is always near at hand, to wit, the exploring needle. The ordinary hypodermic needle is never efficient. A large needle is necessary, but it need not be over one and a half inches in length. It must be small enough to enter between the ribs without unnecessarily enlarging the wound. If fluid is not obtained at the first puncture, a second should be tried at the end of forty-eight hours. If it is thought that purulent fluid or pus is present, the needle should be large enough for its passage. Early evacuation of serous fluid should leave no other evidence than the scar. Always when there is a relapse or slow convalescence, an exploratory puncture should be made to determine if purulent fluid is present. If pus is present, evacuation is demanded. Drainage tubes should be inserted. Incision is called for, although resection may be required. Tonic treatment, fresh air, and sunshine are indicated. Efforts to prevent deformities, so common as sequelæ, should be made. Passive exercise, active exercise, and deep breathing are most essential. The shoulder should be raised from the thorax during sleep, and the clothing must never be suspended from the shoulder of the injured side.

Tendon and Muscle Transference and Arthrodesis in Infantile Paralysis.—E. H. Bradford mentions three methods in the surgical treatment of the results of anterior poliomyelitis—mechanical treatment, muscle and tendon transference, and the stiffening of the joint. The appropriate application of these methods demands both skill and judgment. Although there are many differences in the palsies following anterior poliomyelitis, in many cases certain muscles retain some power which is capable of development. The muscles of the leg often retaining some power are the sartorius, the adductor group, and the hamstrings. The sartorius can be transferred to the rectus without difficulty. When the sartorius is weak, the outer hamstring or adductor can be inserted on the outer side into the fascia and tendon of the extensor cruris. In the paralysis of the muscles controlling the movements of the feet, the combined employment of arthrodesis and tendon transference is most valuable. When all the muscles in the front of the foot are paralyzed, the tendo Achillis can be split and a part be transferred and attached to the peroneus tertius or to the tibialis anticus or both. Tendon transference is valuable in preventing the dropping of the front of the foot, or in cases in which the muscles of the anterior group have been weakened. In valgus and varus deformities, arthrodesis of the midtarsal articulation is of special service. If these measures are used with skill and judgment, the surgeon may look forward to beneficial results in a large percentage of cases.

American Medicine, November 16, 1901.

Infection in a General Surgical Sense.—Daniel N. Eisendrath summarizes his treatment of infection as follows: 1. Ample incisions to lay bare every portion of the infected area, and counterincisions to relieve the collateral œdema. 2. General anæsthesia and a bloodless method of operating whenever possible. 3. The disinfection of an infected wound with strong antiseptics, etc., is of little avail, and may do great harm. 4. We should place most dependence upon free drainage and moist dressings, with the use of mild antiseptics. No powder should be used until granulation is well established. 5. Absolute rest and elevation of the infected area are necessary. 6. After-treatment shall be by secondary suture and early active and passive motion. 7. General treatment consists in the administration of strychnine and whiskey, and in securing proper action of the excretory organs.

Why Should the Oculist Be Consulted?—Fred. D. Lewis believes that the importance of the eye in relation to the general health is not sufficiently understood by most physicians. He thinks that children's eyes should be examined before their hard schoolwork begins. The sense of vision uses up more nerve energy than any other sense that we possess. The waste of nerve energy in overcoming even a slight ocular defect is enormous, when multiplied by years. As a result of eyestrain, the whole physical development of the child may be retarded. The time will undoubtedly come when no physician will treat a case of chronic disease of long standing, such as indigestion, rheumatism, gout, or chronic ovarian or uterine trouble, without first having the patient's eyes examined to see if they are not an important agent in causing the trouble. The writer cites various cases in which the patient was cured of obscure troubles by simply having the eyes attended to, although there had been no subjective symptoms to call attention to the real cause of the disturbance.

Granular Lids.—J. C. Huizinga gives as the predisposing causes of this affection an inflamed and already pathological condition of the conjunctiva; a weak and debilitated condition of the system in which the powers of resistance have become greatly diminished; racial predisposition, noted among individuals belonging to the Irish, Jewish, or Eastern races. The writer speaks of three forms of this disease: (1) An acute light form; (2) A chronic light form; (3) A chronic form with severe complications. In the catarrhal stage the congestion should be relieved. It is well to instil hourly a solution of 22 grains each of boric acid and borax in an ounce each of camphor water and distilled water. An astringent solution should be applied at least once a day by the physician. An ointment of ichthyol may be applied at night before retiring. In the second stage of the disease, the contents of the follicles should be expressed. Some have practised excision of the redundant folds of the conjunctiva. The writer has for years employed metallic electrolysis in the treatment of trachoma. The results are uniformly good and sometimes surprising. In ordinary cases, a cure is accomplished in from four weeks to four or five months.

Philadelphia Medical Journal, November 16, 1901.

Neurasthenia.—Jay G. Roberts calls attention to the fact that neurasthenia and hysteria are two distinct entities. The former is a condition of nervous exhaustion or pathological fatigue, while the latter is a disease with well-marked stigmata. The etiology of neurasthenia includes various factors, although heredity stands at the head. Education is a potent cause, both in the school on account of the modern methods of cramming, and in the home where neurotic parents give way to bursts of temper or continually nag their children. Worry, excitement, overwork, psychic shock, and pelvic disorders in women are among the causes. Men are more frequently affected than women. As to the pathology of this disease, the primary morbid change seems to be not in the nervous system, but in the entire organism. Loss of substance in the cells has been noted. Impaired metabolism and impaired excretion cause autointoxication. This is first felt by the neurons and the nervous system. The most important symptom is fatigue. Headache is very common. Vision is the most often affected of the special senses. Palpitation of the heart is generally present. Gastric symptoms are important. Uncomplicated cases rarely present any difficulty in diagnosis. In the treatment, rest is most important, although absolute rest is seldom indicated. Exercise should be attended to. The diet must be carefully regulated, and tea and coffee are to be avoided entirely. The carbohydrates should be removed from the diet as far as possible. Bathing is very valuable, especially the cold shower or sponge. Constipation should be overcome. Tonics often give excellent results. Morphine should not be used, except in the case of unbearable pain. Much can often be accomplished by suggestion or psychotherapy, and here the personality of the physician is a marked factor for good or evil.

Bovine Tuberculosis and Milk Supplies.—H. L. Russell considers this subject from two points of view: (1) From the standpoint of animal industry, and (2) From that of public health. Successful animal industry, especially with cattle, requires that herds shall be kept free from all taint of this disease. Although the causative organisms found in tuberculosis in man and animals have many common characteristics, there are also differential characteristics which show that they belong at least to different types or varieties, and are not identically the same. The virulence of the bovine type is much greater than that of the human variety. It seems probable that the danger of infection from the bovine to the human would be greater than from the human to the bovine. It will take some time to gather sufficient evidence to prove this point, since the subject cannot be studied experimentally. In the meantime all possible danger should be avoided. The danger comes from meat and milk. Generally speaking, tuberculosis is a disease of the visceral organs and serous surfaces. Often the muscular parts of an animal affected do not contain the seeds of the disease. Cooking will also destroy the vitality of the organism. As to the prevalence of tubercle bacilli in milk, American data are very meager. It is possible that an animal may react to the tuberculin test, and yet deliver milk, even for a long

time, contami[illegible] If the [illegible] at all numerou[illegible] and butter made from the same milk [illegible] the[illegible]. The method of avoiding the consumption of th[illegible] are exclusion and destruction. They [illegible] by sterilization and by pasteurization. Experiments have shown that, when milk is pasteurized in a closed rotating commercial pasteurizer with a ten-minute exposure at 60° C., the vitality of the organism is destroyed, so that no trace of the disease develops. These facts do not hold [illegible] is heated and a surface film is formed. The pasteurization at 60° C. does not change the consistency of the liquid, which is a great advantage.

The Lancet, November 9, 1901.

The Treatment of Ozœna by Cupric Electrolysis.—E. S. Yonge has utilized this method of treatment in fifteen cases. Two patients were cured, five were much improved, six were temporarily improved, and two showed no improvement whatever. Yonge considers the method the best one at our disposal for the treatment of this intractable disease.

A Case of Thrombosis in a Cystic Dilatation of the Saphena Vein.—G. A. Clarkson reports the case which occurred in a man of fifty-one years. He was seen twenty-four hours after the onset of symptoms, and on examination presented redness, swelling, and tenderness on the inside of the leg from the knee down. Over the inner tuberosity of the tibia was a mass the size of a walnut, hard and very tender, and at the junction of the middle with the lower third of the leg was a smaller thrombus. The intervening vein was tender and thickened, but not enlarged or varicose. Rest, hot fomentations, etc., reduced the inflammation. One week later, under ether, incisions were made over the thrombi, the latter dissected out, and the vein ligated above and below. Recovery was uneventful. Clarkson thinks that this case exemplifies very well the superiority of this form of treatment over that by prolonged rest, which is more commonly pursued, for the following reasons: (1) The patient is effectually relieved from the risk of any dislodgment of clot with its accompanying dangers; (2) It prevents extension of the clot to the deeper veins and main venous trunks; (3) It reduces the necessary rest in bed to a minimum; (4) It leaves the patient afterward less liable to a second attack; (5) It relieves the surgeon of the difficult task of deciding when, without incurring undue risk, the patient may begin to use the limb.

The Freezing Point of the Blood and Secretions as an Aid to Prognosis.—A. Ogston describes some experiments he has made along the line suggested by the title of his paper, using the term cryoscopy as the designating name of the process. He has experimented with blood, urine, and saliva, using Beckman's freezing-point apparatus which is figured and described in the text. Connected with the apparatus is a thermometer of a short range but large enough to be divided into numerous registers. The freezing-point of normal blood is determined, and then that of the various fluids examined is compared with this standard. In cases in which the point is below normal operation is contraindicated. Van't Hoffs and Raoult [illegible] pointed out that fluids freeze at a lower temperature [illegible] proportion to the impurities dissolved in them. Ko[illegible] applying the law to the blood and urine, showed that normal blood possessed a fixed freezing-point of 0.56° C. [illegible] that of distilled water which forms the zero of that [illegible] scale. From this point it does not vary [illegible] than by one-hundredth of a degree up or down. [illegible] a fluid varying in its freezing-point [illegible] from −1° to −2° C., in proportion to the [illegible] that it contains in a state of solution. Con[illegible] stated. So long as the blood is healthy and [illegible] adequately eliminated, it retains, as already said, its normal freezing point, viz., [illegible]56°, or within [illegible] of that figure, varying, that is to say, from −0.55° to −0.57°, but if elimination becomes defective, the freezing-point sinks below this, to −0.58°, [illegible] even to −0.71° in one case [illegible] by Kummell. The attention of these observers appears to have been mainly directed to the purification of the blood effected by the kidneys, regarding the measurement of which our present knowledge is admittedly defective and where consequently, the value of cryoscopy promises to be great.

Acute Dilatation of the Stomach with an Account of Two Cases.—The cases are reported by C. R. Box and C. S. Wallace. They are respectively described as follows: Case 1.—Lacerated wound of the knee [illegible] of the leg and the ultimate amputation of the limb; acute dilatation of the stomach and of part of the duodenum. Case 2.—Pleuropneumonia with [illegible] symptoms acute dilatation of the stomach [illegible] duodenum. The authors suggest that in acute dilatation of the stomach two factors [illegible]. The first is a paralytic condition of the viscus which leads to distention, and the second an obstruction produced at a certain stage by the pressure of the distended organ upon the duodenum on the front and left of the spinal column. The presence of the power to vomit in these patients is no proof that the stomach is not paralyzed. The condition has been mistaken for (1) Intestinal obstruction, (2) Perforative peritonitis, (3) Perforation of bowel with encysted abscess, (4) Pancreatic cyst, (5) Uræmia, and (6) Post-anæsthetic vomiting. 1. Of obstruction it doubtless is a form, but of obstruction high up, with obtrusive abdominal signs in the form of gastric dilatation. It must be noted, however, that diarrhœa is present and severe in some cases. 2, 3, and 4. The intense abdominal pain which is usually present, the vomiting, the increasing abdominal distention, and the very marked collapse closely mimic general peritonitis. The position of the percussion dulness in the lower part of the abdomen and right iliac region may or a superficial examination appear to confirm this suspicion. The enormously distended stomach has even been mistaken for an encysted abscess. 5. The incessant vomiting, the partial suppression of urine, the occasional albuminuria, the condition of somnolent delirium which may mark the approaching termination, and the "collapse" temperature which is sometimes but not always present, may well give rise to suspicions of uræmia. 6. In those cases which occur after operations there is a great danger of attributing the vomiting to the anæsthetic and the collapse to the operation. Careful examination of the abdomen in these cases is the only safeguard.

British Medical Journal, November 9, 1901.

A Case of Recurrence of Laryngeal Papillomata in a Child After Tracheotomy.—E. Mansel Sympson reports this case. The patient was a girl aged seven years, who had been suffering for about two and one-half years from laryngeal obstruction due to multiple papillomata. Tracheotomy was performed, but the obstruction returned and the larynx became choked with papillomata. She was operated on again, and the papillomata were completely scraped away with a sharp spoon. She is now in excellent health and voice.

Treatment of Intussusception by Inflation and Succussion.—E. Blacker describes this case. The child showed all the usual signs of the malady, vomiting, tenesmus, with blood and mucus passing from the anus. This attack was the sequel to an attack of diarrhœa. No fæces had been passed for hours. The child's condition was precarious. The rubber part of an ether spray apparatus was attached to a No. 12 gum-elastic catheter. The point of the catheter was passed through the anus, and air was forced steadily into the rectum. The catheter was gradually passed higher and higher, till it seemed unwise to go farther. The child was then gradually inverted, and gentle succussion was practised. Almost before the inversion was complete, there was a forcible escape of air and fæces. All unpleasant symptoms vanished, and the relief was complete.

The Comparative Frequency of Syphilis Among the Circumcised and the Uncircumcised.—Arthur Powell of Bombay states that the police of that city are a mixed force of Hindus and Mussulmans in the usual proportion of 3 to 1. In the past nine years, there have been admitted to the police hospital 200 cases of primary syphilis from an average strength of 1,570 Hindus, and 105 cases from an average strength of 523 Mussulmans. Had the incidence been the same, the Mussulmans should have had only 71 cases. According to these numbers, instead of protection in equal populations, there should be more than 150 cases of syphilis among the circumcised for 100 among the uncircumcised. These figures are opposed to one's preconceived opinion. The proportion of married men is much the same in both sections. The comparative sexual morality is a negligible quantity.

Some Symptoms Produced by Tumors of the Optic Thalamus, with a Case.—J. Michell Clarke gives the following symptoms which occur in some cases of tumor of the optic thalamus, and which are valuable for diagnosis: (1) A sensation of heat or burning in the opposite upper extremity; (2) A marked intentional tremor in the same limb, absent during rest, and exactly resembling during movement the tremor of disseminated sclerosis; (3) Hemiplegia of the opposite side, of gradual onset, affecting the upper extremity only for a considerable time and predominating in this limb throughout. Other symptoms must of course, be considered in making the diagnosis. Instead of the intention tremor, there may be choreiform movements. When the intention tremor is present, a differential diagnosis must be made between tumors of the optic thalamus, of the corpora quadrigemina, or of the

cerebellum. There is another symptom said to be characteristic of lesions of the thalamus, but apparently not invariably present; this is a loss of the emotional movements of the face, while the voluntary movements are preserved. The writer then reports a case remarkable for the absence of the three cardinal symptoms of intracranial tumor—severe headache, vomiting, and optic neuritis.

Berliner klinische Wochenschrift, October 28, 1901.

The Effect of Biliary Retention on the Secretory Activity of the Gastric Cells.—S. Simnitzky made eighty-one analyses of the gastric contents in catarrhal jaundice, hypertrophic cirrhosis, Weil's disease, and obstructive jaundice, due to a pancreatic tumor. He also made a series of observations on a number of dogs with œsophageal fistulæ, and with a portion of the stomach isolated in the Heidenhain-Pawlow method. The results of both methods of investigation showed that there is an intimate connection between the biliary organs and gastric secretion, retention of bile always inducing gastric hyperchlorhydria, which subsided again when the gall-passages returned to a normal state.

False Tumors of the Abdomen.—Max Einhorn avoids the term "phantom tumor," because what he describes is not the tympanitic distention seen in hysterics, and to which this term is applied, but a much more deceptive condition. Out of a total of 6,045 patients, the author observed it in eight men and thirty-four women, and five characteristic case histories are given in brief. In each, there was a mass in the upper part of the abdomen, which might easily have been mistaken for a new growth. The structures simulating such a condition may be a prolapsed left lobe of the liver, a thickened and exposed abdominal aorta, hypertrophy of isolated portions of the abdominal musculature, or adhesions (?) about the lesser curvature of the stomach. The following points are of value in making the differential diagnosis: The surface of the tumor is smooth, or at least presents no distinct nodules, and at times it may wholly or in part elude palpation. Enteroptosis is usually associated with it, while the condition is likely to be of long standing, and may occur at any period, from late youth to old age. In difficult cases, time gives the only absolute clue, and observation during several weeks will show increase in size of the tumor and aggravation of the symptoms in the case of a true neoplasm, while apparent tumors remain unchanged, or may, under suitable treatment, show improvement. Enteroptosis is a potent etiological factor, and improving the nutrition is of great importance in the treatment.

Münchener medicinische Wochenschrift, October 29, 1901.

A Case of Puerperal Sneezing.—K. Heil describes the case of a woman who, during two successive pregnancies, suffered severely from prolonged attacks of sneezing. This was so violent that in the first instance abortion resulted, but when the trouble recurred it was checked completely by the local application of 5-per-cent. cocaine solution. The author's explanation of the phenomenon is that the circulatory disturbances accompanying pregnancy caused relaxation and congestion of the nasal mucous membrane, which, in its turn, led to pressure on the filaments of the sensory nerves with the production of sneezing.

Some Observations on the Specificity of Bacteria.—P. Klemm, in a contribution intended mainly as a refutation of Jordan's observations on the organism of erysipelas, says that there are no radical differences in the effects produced by the various bacteria after their penetration into the human body. Totally different irritations can produce similar results, and erythema and serous infiltration, diffuse or in vesicles, follow mechanical injury, burns, freezing, chemical action, bacterial infections, etc. According to the severity and duration of the injury, the tissues may completely recover or go on to gangrene, necrosis, and liquefaction. There is, therefore, no obligatory specificity of the bacteria, but there is facultative specificity, and the action of various bacterial forms produces characteristic reactions in the tissues.

The Genesis of Tumors, Tuberculosis, and Other Organic Diseases After Blunt Trauma.—Jordan says that from the material available, the conclusion seems justified that in a general way blunt trauma may be of effect in producing tumors, but exact knowledge as to the actual part played is wanting. The latest statistics show great unanimity in indicating that a single injury only very rarely has the formation of tumors as a result. In 502 recorded cases of carcinoma at the clinic of Tübingen, not a single one was referable to the traumatism, so that it seems that in this form of growth such injuries play only a small part. The percentage of traumatic sarcomata is very small, but still is larger than that for cancer. In tuberculous joint diseases it is impossible to be sure that the disease did not exist before the injury, and was aroused from its latency by the formation of a *locus minoris resistentiæ*. Osteomyelitis may occur in close connection to injury, as also appendicitis, though in both cases the evidence cannot be regarded as conclusive unless the symptoms develop very soon after the accident.

Deutsche medicinische Wochenschrift, October 31, 1901.

The Theory of Fat Staining.—L. Michaelis says that a general rule may be expressed about as follows. Fat solubility and water solubility are reciprocal. Markedly basic or acid bodies are more soluble in water than their indifferent mother substances, and water solubility decreases and fat solubility increases proportionately as acidity or basicity is decreased by the abstraction of salt-forming groups. More definitely, the neutral dyes are, as a rule, specific fat stains. There are also weakly basic and weakly acid bodies which stain fat, viz., first, those which are so faintly acid or alkaline that the fat can extract the free base even from their salts, and secondly, those whose reactions are a little more pronounced, so that only the free base or acid has staining properties.

The Excretion of Typhoid Bacilli in the Urine.—Schüder examined the urine of twenty-two typhoid-fever patients, and found the typhoid bacillus present in five (22.7 per cent.). In all, 671 examinations were made, and the results showed that typhoid bacilli may be excreted in the urine in enormous numbers. It is particularly the more severe cases with albuminuric complications that are likely to give positive results, but the organism may be found even in less serious forms. The excretion of the bacilli may take place during the illness itself, or during convalescence. The latter seems to be the more common, and even weeks after defervescence, typhoid bacilli may be found in the urine. The practical application of these conclusions, which are confirmed by those of various other observers, like Chantemesse and Widal, Merkel and Goldschmitt, and others, is that very thorough disinfection of typhoid urine is necessary for a period of weeks after defervescence; and that this excretion, no less than the stools, is always to be regarded as a source of danger. It is particularly those who come in personal contact with the patient, *e. g.* in giving baths, who are exposed to infection from this source, and they should always be warned of its possibility.

Treatment of Varicose Ulcers by Fascicular Dissociation of the Sciatic Nerve.—A. Silvy shows that the varicose ulcer has a triple pathogeny—arterial, venous, and nervous. On account of the fact that this ulcer is a consequence of a disturbance of the trophic nervous system, he advocates as a rational method of treatment the fascicular dissociation of the sciatic nerve. The incision is made and the nerve exposed. It is supported on a blunt instrument, while its fasciculi are dissociated by a sound. The length of the nerve thus treated ought to be from 4 to 5 cm., and each one of the bundles separated ought to have a diameter of about 3 mm. In this operation only the fibrous tissue is torn; the continuity of the nerve is not destroyed. Sometimes the vessels are torn, but the hemorrhage is soon arrested. The operation is simple and rapid, and may be performed for this trouble, whatever may be the position of the ulcer.—*Journal de Médecine de Paris*, November 3, 1901.

Sarcoma of the Breast, Coincident with a Large Goiter.—H. Morestin reports this interesting case. The patient was a woman of fifty years. Since her youth, she had had a goiter which had developed very much during her two pregnancies, but since the last one it had remained stationary. The goiter was about the size of two fists, and occupied the right lobe. Palpation showed it to be a large thyroid cyst. It was not for the goiter, however, that the patient sought aid, but for a tumor of the left breast. This she had also had for a long time, and it had had two distinct periods of evolution. Over twenty years before she had noticed a small, hard nodule above the breast. At one time she had it treated by caustics; and although it had sloughed off, it returned again. It had now attained the volume of an adult head. The diagnosis of sarcoma was made, and this was later confirmed by histological examination. The tumor was extirpated, and a large wound was left. The goiter was incised and evacuated, and the large skin flap thus obtained was grafted on to the chest wound. The result was excellent, but the prognosis is undoubtedly bad, as recurrence is probable. This case is an example of the plurality of neoplasms, a coincidence of a benign and a malignant tumor associated in the same subject.—*Gazette des Hôpitaux*, October 31, 1901.

Surgical Interventions in Cases of Dystocia from Fibromata.—André Boursier states that fibromata can cause

dystocia in several ways. They may cause abnormal presentations (fetal dystocia); they may disturb uterine contractions (uterine dystocia); or, by their position, they may present a mechanical obstacle to the passage of the fœtus (fibrous dystocia). This last condition is most often caused by fibromata in the lower part of the uterus and the cervix. Pregnancy modifies fibromata in relation to their structure, their consistence, and their position. Consequently, the diagnosis of dystocia is often made only at term of or even during labor. Both fetal and uterine dystocia are suitable for obstetrical intervention. Fibrous dystocia calls for the same treatment when it is not severe. In severe cases it should be treated by surgical intervention. Fibromata of vaginal origin should be removed by the vaginal route. Those of the pelvic-abdominal type ought to be operated on through the abdomen. Symphysiotomy ought to be absolutely rejected in the treatment of fibrous dystocia. Cæsarian section is justifiable only in exceptional cases. It is, on the contrary, a good operation when it can be efficiently completed by myomectomy. The Porro operation ought to be reserved for certain particular cases, which are well limited. Total abdominal hysterectomy, a radical operation and truly curative, constitutes the method of choice and ought always to be employed when possible, whether the child be living or dead.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, November 3, 1901.

A Large Suppurating Hydatid Cyst of the Neck.—Léon Thévenot declares that hydatid cysts which develop in the soft parts of the neck, outside of the thyroid gland, constitute a rare affection. He reports the case of a man of fifty-five years who had noticed the presence of a tumor in the left side of the neck for the last four years. There was nothing significant in the family history. The growth had developed without apparent cause, without pain, without functional troubles, and, in fact, it was only by chance that the patient had discovered it. It was at first about the size of a hazelnut, and was deeply situated in the upper part of the neck. It was freely movable, and entirely independent of the superficial parts. It continued to develop until within two years it had reached the size of an apple. Its growth then ceased. After an attack of grippe, severe general symptoms developed, high fever, gastric disturbance, headache, and a systemic condition that was rather alarming. At the same time the tumor became larger and painful. On examination, there was seen a large phlegmon involving the left half of the neck. The region was hot, red, and painful. The skin was œdematous. Fluctuation showed the presence of pus. The abscess seemed to point toward the skin. The diagnosis, as far as the determination of a cyst was concerned, was easy enough; but its precise nature was more difficult to determine. An operation was performed. The cyst was found to be hydatid; it was evacuated and drained, and the patient made a good recovery.—*Gazette des Hôpitaux Civils et Militaires*, October 29, 1901.

The Scottish Medical and Surgical Journal, November, 1901.

The Study of Individual Cases.—Charles W. Cathcart urges the clinical study of surgical cases for undergraduates. Recollection of what a teacher says is one thing, and valuable in its way, but actual knowledge acquired by personal observation is a totally different thing, on an infinitely higher platform. He warns his students that at class examinations he will, in addition to having a written paper upon subjects which have been discussed at lectures, expect them to tell from naked eye and microscopic specimens what they are, and to give the clinical history of the patients from whom they were taken. Instruments will be shown, and the students will be asked to explain the uses to which they were put during the session, as well as the purposes for which they are usually applied. They will be asked to apply some bandage or splint, and to answer questions about what has been seen in ward visits and clinics.

Some Observations Upon Dietetics in Pulmonary Tuberculosis.—Noel D. Bardwell made researches on the effects of ordinary and forced feeding upon metabolism in tuberculous patients. He found (1) That patients when not closely supervised did not get a sufficient amount of food, though plenty was given, so that patients on the hospital routine improved quicker when under closer observation; (2) The patients in the special sanatorium wards did excellently in every respect. The diet, three meals daily, was made up of meat, 7 oz.; bacon, 2 oz.; egg, 1 oz.; milk, 3 pts.; butter, 3 oz.; bread, 7 oz.; sugar, 1 oz.; pudding, 5 oz.; vegetables, 6 oz.; (3) Patients on this diet, when given a considerable larger amount of food, such as 6 or 7 pints of milk, 12 oz. or more of meat, in a few cases with several ounces of somatose or lactose in addition, did not give such satisfactory results. Weight was gained at a greater rate, but often was associatep with deterioration of general health and laboratory results indicating deranged metabolism.

Heredity.—Robert Park holds that environmental influences can reach the embryo only through the medium of the vascular and nervous system of the female; and similarly, in both male and female, the germplasm is protected by the somatic structures, and it is but reasonable to suppose that only very intent or very prolonged and repeated alterations of these can effect alteration of it. And then, when such has been achieved, it must be seized upon by natural selectivity before becoming phylogenetically efficient to induce variation. The rôle of the parent, thus, in regard of the germplasm is rather that of a trustee than of a testator, and it would be difficult to exaggerate the fruitfulness of this idea from an ethical point of view. The great bulk of acquired characters are not inherited, as a matter of course, for if they were, there would be no stability of species. Only those are transmitted normally which are, so to speak, approved for the species by N. S. (letters used conventionally apparently to personify the unknown influence exerted), and which thereafter succeed in running numerous dangers in the preconceptional and ante-natal struggles for existence. The exceptions to this must be classed as abnormal, howsoever numerous they may be.

New Orleans Medical and Surgical Journal, Nov., 1901.

Thirty Cases of Acute Lobar Pneumonia with Twenty-nine Recoveries.—E. D. Newell ascribes his excellent results to the following treatment: A dose of five to ten grains of calomel was given and was followed by magnesium sulphate, if the bowels did not move freely. Strychnine sulphate ($\frac{1}{30}$ grain) was begun on the first day in every case, and given every fourth hour day and night. When the pulse was 135 or above and weak, $\frac{1}{30}$ grain strychnine sulphate was given every four hours; when above 145, every three hours, and when 160, and scarcely perceptible at wrist, and when the patient was cold, clammy, dimly conscious and panting for air, then $\frac{1}{30}$ grain strychnine was given every three hours, and one ounce of the best whiskey every two hours.

Malarial Hæmoglobinuria.—Otto Lerch says that in the treatment of this condition, it must be borne in mind that quinine has no curative influence; it destroys the plasmodia, but if enough has been taken to accomplish this object, we aggravate the case by adding one more toxic substance to those already present. Absolute rest is of paramount importance. Fresh air is the next indication. The primary lesion is an intense anæmia; the red blood corpuscles are enormously decreased in number, their chemical composition is changed, and they are especially deficient in hæmoglobin, so that the physician should see to it that every corpuscle that is able to carry oxygen should have a chance to grasp it. Pure air is the best thing, but inhalations of oxygen may also be tried. The emunctories must be cleared, the anæmia is to be treated with iron and arsenic, and the diet must be carefully regulated.

The Ultimate or Predisposing Cause of Dermatoneuroses.—J. N. Roussel makes a distinction between nerve matter and nervous matter, comparing the former to the storage battery and its component parts, and the latter to the current. The nervous matter is an example of the homogeneous in nature and of the unstable. All functions are presided over by nerve centers, in which is locked up a quantity of the unstable nervous matter, placed most favorably for being acted on. Every excitation of a nerve center reduces, for a time, this quantity of locked-up nervous matter, leaving a decreased readiness to undergo changes when disturbed, as well as a decreased stock of molecular motion to be liberated. The perfect execution of the functions of any particular organ or set of organs depends ultimately on the perfect development of their governing centers in the brain. The nerve matter also, as well as the nervous matter, being in the beginning homogeneous and unstable, must necessarily, in the process of development, undergo a change to heterogeneity or stability properly to govern the more unstable nervous matter; and, according as the development of these specific portions of nerve matter is or is not perfect, so will the function over which they preside be normal or otherwise. The proposition follows that in that condition of unstable equilibrium which these centers obtain from lack of development lies the ultimate or predisposing cause of all the affections of the skin and other organs depending upon derangements in the nervous apparatus, and their cure lies in our ability to restore their equilibrium when disturbed.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Sixty-fifth Regular Meeting, Held on Friday, October 11, 1901.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

A Case of Tuberculous Pericarditis, with Presentation of Specimen. Reported by Dr. BEVERLEY ROBINSON. The patient was a colored man, twenty-three years old, a native of the United States, who was admitted to the hospital on April 15, 1899. His family history was negative. He was formerly a heavy smoker, but for a number of years had neither smoked nor drunk. He had gonorrhœa two years ago. There was no history of syphilis or rheumatism.

The patient considered himself perfectly well until one week previous to his admission, when he thought he "caught cold." He had no chill, but complained of a pain in the lower chest, anteriorly, and great difficulty in breathing. He had a short cough with scanty expectoration, and the sputum was not rusty. He could lie on either side, but did not rest comfortably on his back.

Examination showed an area of dulness, about the size of the palm of the hand, in the region of the left nipple, with a few subcrepitant and sonorous râles, and prolonged and high-pitched breathing. There was a corresponding area in the posterior chest and high up in the left axilla. The tongue was moderately coated. The pulse was rapid (120) and irregular. His temperature on admission was 103° F.; respirations, 30. There was considerable pain on both sides of the chest. The urine was acid; sp. gr., 1030; it contained 2 per cent. of albumin, together with hyaline and granular casts; no sugar.

On the second day, dulness and feeble breathing were found at the right base, posteriorly. A needle was introduced and clear fluid withdrawn. On the following day the heart sounds were very feeble. Cardiac dulness extended two inches to the right of the sternum. The apex could not be made out, and no murmurs were heard. The Widal test gave a negative result. On April 25, the urine showed 15 per cent. of albumin and many casts. The cough was becoming more troublesome. Sibilant and sonorous râles were heard over both chests. There was no fluid in the right chest.

On May 3, a radiograph verified the area of cardiac dulness mapped out by percussion. The dulness extended four inches to the right of the mid-line at the fourth rib, and eight inches to the left. At the second interspace, it extended three and one-half inches to the right, and five inches to the left. In the nipple line the dulness extended to the seventh rib.

On May 4, 1899, the pericardium was aspirated in the fifth space, two inches from the mid-line, and forty ounces of a reddish-brown fluid withdrawn. Following this, the respirations became easier and deeper, and there was great improvement in the force and character of the heart-beats. Four days later he developed a phlebitis in the left leg, and the pericardial friction sounds became more distinct. On May 17, the expectoration was blood-streaked. No tubercle bacilli were found. The pericardium was again aspirated, and forty ounces of maroon-colored fluid obtained. After aspiration, cardiac dulness extended five inches to the right and five inches to the left of the mid-line. The temperature was now more irregular, falling to normal in the morning and going up to 101° or 102° F. in the afternoon. A phlebitis developed in the right forearm. The friction sounds were moderately loud.

During the next two weeks, the patient was much improved and was able to sit up in a chair. The heart's action was more forcible and regular. On June 2 fluid was found in the pericardium by exploration. The temperature remained below 101° F., but was still irregular. The urine contained from 50 per cent. to 60 per cent. of albumin and many casts. Its specific gravity ranged from 1020 to 1025.

On June 20, the pericardium was again aspirated, and twenty-eight ounces of brownish fluid obtained. The bacteriological examination of the blood was negative. The heart's action was rapid, feeble, and irregular. On July 16, a radiograph showed that the right border of the heart extended beyond the right nipple line. A needle was inserted just below the right nipple, and brownish fluid found, which contained tubercle bacilli. The patient died on July 18.

After death, the heart showed nothing abnormal except a thick coating of fibrin and granulation tissue which contained tubercle bacilli and giant cells. This layer measures from 1 to 2 cm. in thickness all over the surface of the heart. It is quite spongy and rough, with long shaggy masses of fibrin hanging from the outer surface. The pericardial sac is thickened quite symmetrically and distended so as to form a large oval sac, with its greatest diameter in a transverse position. The dimensions are 20x18x15 cm., roughly. The heart is not adherent to the pericardium, but hangs quite free in the sac. The walls of the pericardial sac are from 3 to 5 mm. in diameter. Microscopical sections show tubercle tissue and giant cells.

The bronchial lymph nodes are tuberculous, which suggest the source of infection, many of the cases showing advanced lymphatic tuberculosis, with a beginning pericardial lesion.

Dr. ROBINSON referred to the comparative rarity of cases of tubercular pericarditis, and discussed the question of the position of the heart when there is pericardial effusion. In purulent pericarditis, which more particularly interests the surgeon, it has been pretty well determined by observation and experiment that the heart is compressed against the thoracic wall. With serous exudations, however, it is more difficult to make out the exact position of the heart. It is not easy, at times, to distinguish between an enlarged heart and a pericardial effusion unless the latter be very considerable in quantity. When the heart is suspended in a serous exudation, there is only a thin layer of fluid between its anterior surface and the pericardium; and hence, on aspiration, only a small quantity of fluid may be obtained even in cases where the effusion is very great. This point was emphasized in a paper by Dr. Shattuck of Boston, which he read before the Association of American Physicians some years ago.

With reference to the site of puncture in cases of pericardial effusion: The classical site is in the fourth or fifth interspace, two inches from the mid-line. Sometimes we get fluid at that point, but there are observers who think it wiser and more judicious to puncture rather farther toward the left, while in some cases the fluid extends considerably beyond the right sternal margin.

As regards the danger of puncturing the heart, Dr. Robinson said that, while it was not a desirable accident to happen, he recalled one case where his aspirating needle punctured the ventricular wall without apparent injury.

In connection with effusions in the pericardial sac the questions arise, When shall we do the radical operation, and when should we depend on simple puncture? In the purulent cases, the latter procedure will probably be of only temporary value, as the fluid rapidly re-accumulates. In the case just reported, life was doubtless prolonged by the aspirations. In purulent pleural effusions, it is true, the patient may ultimately recover after two or three tappings; but this same rule cannot be applied to the heart, and is even very exceptionally to the pleura;

it is wise to remember that there is only one heart, while there are two lungs.

In the case of tubercular pericarditis, which came under the speaker's observation last spring, the pericardial effusion was left undisturbed. The autopsy showed a layer of fat underlying the cellular tissue and infiltrating the heart muscle. In that case, life might possibly have been prolonged by aspirating. Dr. Robinson said that, when once the diagnosis of tubercular pericarditis is established, the case should either be aspirated or turned over to the surgeon.

Dr. GEORGE L. PEABODY said that, in his experience, tuberculous pericarditis is likely to be accompanied by very copious effusion. When the fluid reaccumulates after one or two tappings, especially in youthful patients, one is apt to suspect the tuberculous character of the disease. As to where the heart lies in cases of serous effusion, the speaker said he had found that the organ follows the ordinary law of gravity, and is usually found in the most dependent portion of the pericardial sac, the subject lying upon its back. When the heart is much enlarged, there is great liability of puncturing it. Dr. Peabody said, he could recall several instances where this accident occurred; but it is not apt to be followed by serious results, if the needle is clean and not of unusual size. He did not think it advisable, in cases of pericardial effusion, to make an open wound and establish drainage, unless there was suppuration. As to the site of puncture, the favorite point is to the left of the sternum, in the fourth or fifth interspace. When there is an enormous area of dulness, we will probably get fluid by puncturing to the right of the sternum, and are less likely to injure the heart.

Dr. EDWARD G. JANEWAY said that, as a rule, he thought it was preferable to select the left side for puncture, being careful to avoid the internal mammary artery. We should endeavor to ascertain beforehand from the history whether or not the heart was enlarged; if it was not, we might go lower than the fifth interspace and strike upward. The speaker said he preferred the needle to the trocar and canula for the purpose of tapping the pericardial sac.

As regards puncturing the heart, Dr. Janeway said he had done this occasionally for diagnostic purposes; he recalled one case, that of a man, who was cyanotic and in a desperate condition, where a needle was inserted for the purpose of determining whether the area of dulness was due to a dilated heart or to the presence of pericardial fluid. In another case, one of emphysema, he introduced the needle into the right ventricle without doing any harm. A few years ago a physician in Brooklyn, Dr. Westbrook, proposed aspiration of the right heart for the relief of overdistention. In the case of serous effusions of the pericardium, Dr. Janeway thought that aspiration was sufficient, while in the purulent cases an incision and drainage would be preferable.

Dr. W. GILMAN THOMPSON said he certainly was not in favor of surgical intervention in cases of simple serous exudations into the pericardial sac. Aspiration was sufficient and preferable to an open wound. He mentioned a case in which he had accidentally punctured the heart, without resulting harm.

Dr. ROBERT ABBE said that if he was brought face to face with a case of pericardial effusion of the tuberculous type, and the symptoms were urgent, he would feel strongly inclined, on general principles, to advise surgical interference. We know that purulent effusions are perfectly curable by free drainage of the pericardial sac, and that to produce fibrous occlusion of the sac, as we do with the peritoneum, is in nowise disastrous. The speaker said that while he has had no experience with this operation personally, he thought it could be undertaken with a fair expectation of success. When the effusion is serous, simple aspiration would probably be sufficient.

Dr. WILLIAM M. POLK said he wished to add his testimony to the innocuousness of puncturing the heart. In 1878, he saw a case of pneumonia on the left side. The dulness was attributed by mistake to the presence of a pericardial effusion, and a needle was introduced. No fluid was found, and the movements of the needle showed that it had entered the heart muscle. Subsequently, the patient died of pneumonia, and the autopsy revealed the fact that the left ventricle had been punctured without apparently doing any harm. There was a simple puncture, without any tearing of the muscle.

Dr. PEABODY reported the case of a middle-aged man who was suffering from rheumatic pericarditis. The pericardial sac was apparently much distended, the area of dulness increasing day by day, so that it was reasonably certain that fluid was present. Upon the insertion of a needle, however, no fluid was obtained, and the man complained of a great deal of pain. It was thereupon decided to postpone further efforts until the following day. Subsequently, upon examining the needle, it was found that its tip was tightly plugged by a bit of hyaline cartilage, which had evidently prevented the entrance of fluid. It had lodged there during the introduction of the needle, which had been passed through the edge of the costal cartilage. The outcome of this case, Dr. Peabody said, was interesting. After the ineffectual attempt at aspiration, the fluid in the pericardial sac rapidly subsided, and the patient recovered without the necessity of further puncture.

The President, Dr. BRYANT, said he thought the best site for puncturing the pericardial sac was between the sixth and seventh ribs, close to the left edge of the sternum; at this point we escape the mammary artery without, and there is no danger of wounding the pleura, or heart, as the parts concerned bear a substantially normal relation with each other. The speaker said there were cases of suppurative pericarditis on record which had been treated by free incision.

The Interpretation at the Bedside of Clinical Laboratory Tests.—Dr. W. GILMAN THOMPSON read an interesting paper on this subject, in which he discussed the value of the various laboratory tests which are now commonly employed in connection with clinical work.

Dr. JAMES said that the growing tendency on the part of the profession to lean too heavily upon laboratory examinations as aids to diagnosis was a result of the natural craving for some more simple and certain method of establishing the nature of disease than by the use of the old-fashioned clinical examinations.

In a great many cases, however, such confidence leads to errors, chiefly from failure to realize two facts: First, that in most cases a laboratory test, the result of which is negative, does not exclude the presence of the disease in question. Second, that in most cases the personal element of the examiner enters into the result just as it does in the case of auscultation and percussion, and other ordinary methods of investigation. The value of a Widal test in typhoid fever, or of an examination of blood for the malarial organisms, depends largely upon the personality of the examiner.

The speaker said that during the past few months he had seen a number of cases in which the correct diagnosis would probably have been arrived at, had the attending physician limited himself to the simpler methods of investigation, and not had his mind clouded by the failure to get a positive laboratory report.

Dr. James said that he did not wish to disparage in any way the excellent work that is being done in the laboratory, nor the influence of this work in aiding thorough medical study. He wished merely to emphasize the necessity of a more critical judgment on the part of practitioners of medicine in estimating at the bedside the value of these tests, and in coming to know more clearly their limitations. We should probably make fewer errors of this kind if we bore constantly in mind the

excellent advice of Sir Thomas Browne, when he urges to "look not for whales in the Euxine sea."

Dr. ROBERT ABBE said that, while he resorted to the test-meal in cases of suspected cancer of the stomach, he regarded this measure as of comparatively insignificant value. In cases of early carcinoma of the stomach, when we most need its assistance, it fails us, and when the disease has advanced to the point where the clinician recognizes it, the condition is usually inoperable, except for palliative measures.

Increased leucocytosis, Dr. Abbe said, he regarded as a very valuable aid in the diagnosis of suppurative conditions, but it is secondary in value to the temperature chart. Blood examination furnishes us with early and accurate information to differentiate other processes occurring after surgical operations, and in the diagnosis of such conditions as malaria or typhoid, coming on during convalescence.

Dr. HERMANN M. BIGGS said that in determining the value of these clinical tests, there are a number of factors that are often overlooked. First, there arises the question of the accuracy of the procedure. In the New York Health Department cases are of common occurrence where wrong bacteriological findings resulted from the fact that the physicians did not carefully follow directions in preparing the specimens. It is of the greatest importance that the directions given, as to preparation of all kinds of microscopical bacteriological specimens, be exactly followed. Then, again, we should be able to place absolute reliance upon the competence of the bacteriologist. Unless the examiner is thoroughly capable, we are certain to be led astray, and the examinations are worse than worthless. Again, a distinction must be made between a positive result and a negative result. A positive result, made by a competent man, leaves no question as to its interpretation. Negative results may be valuable, or they may be absolutely valueless. The results of a blood examination, when they are positive, are of great value.

Dr. Biggs said that many errors in the examination of cultures from the throat for the diphtheria bacillus were due to the fact that the cultures were not properly made. Ofttimes the practitioner does not take the time carefully to read the instructions of the Health Board, or else fails to follow them.

Dr. CHARLES L. DANA spoke of the relation of uric acid to lithæmia and kindred conditions. He had observed a class of patients, generally middle-aged or elderly, who had neurasthenic symptoms, such as migraine, insomnia, mental depression, vague pains, paræsthesia, etc. The symptoms progressed rather steadily, often becoming associated with some evidences of arterial sclerosis; sometimes they developed a slight amount of glycosuria. The symptoms in these cases were always associated with a real and constant increase of uric acid. This appears to be the most constant factor in metabolism discovered. He did not attempt to interpret it.

Dr. Dana said he had examined the urine for indican in a routine way for many years, but only occasionally had it apparently borne any relation to the condition of the patient. In a recent case of sensory multiple neuritis there was persistent and marked indicanuria, and when this disappeared, after several months' treatment, the neuritis gradually abated.

Dr. Dana said that some years ago, while investigating the subject of the alcoholic wet-brain or serous meningitis, he found that with the ordinary wet-brain there was no leucocytosis; but when true meningitis developed, the leucocytosis appeared. This proved of much help in the diagnosis, and it is also very valuable in the recognition of obscure cases of serous meningitis and encephalitis, and to determine the presence or absence of brain abscess.

Dr. JANEWAY said he was in general accord with the statements contained in Dr. Thompson's paper, and had long felt and said so. He had seen many failures result from a single bacteriological examination, and even in very good laboratories, at times, mistakes are made. He recalled a case of post-cæcal abscess from a gangrenous appendix which had been positively pronounced typhoid fever by the pathologist, who reported that there was no leucocytosis and that he had obtained a distinct Widal reaction, and that the case was an undoubted one of typhoid fever. The pathologist in this case was a reliable man, and it is probable that he got his specimens mixed, as no Widal reaction could be found, and the leucocytosis was 34,000, when I saw him.

During the past three years, Dr. Janeway said, he had seen three cases of typhoid fever which were mistaken for appendicitis and operated on, and had knowledge of other similar mistakes. Such an error, he thought, could usually be avoided by a leucocytic count, as a low leucocytic count should, as a rule, make one delay, unless in a doubtful case of urgent nature. In malarial conditions, the blood examinations often give unsatisfactory results and must be repeated. In one case where the clinical symptoms of malaria were very clear, the parasites were not found in the blood until the third and fifth examinations. Dr. Janeway said he could recall four cases where tubercle bacilli were found in the sputum of persons who gave no other evidences of tuberculosis at the time or subsequently. How did they get there? One case was that of a boy who was brought to the hospital in an unconscious condition. He had a high fever, and râles were heard over the chest. His sputum was sent to the laboratory, and the report came back that it contained tubercle bacilli. Prior to this, his history was obtained and showed that he was ill with a fever such as several of the family had, one having died with typhoid fever. The case proved to be one of typhoid fever, and there were no further evidences of tuberculosis. In another case, one of bronchitis, the tubercle bacilli were found in the sputum by one observer. Examinations in two laboratories were negative, and chemical phenomena warranted the diagnosis of bronchitis only.

The search for malarial parasites in the blood should be made by one who is thoroughly competent. In a case which came to the speaker's knowledge, the patient, a woman, developed a high fever after childbirth. A specimen of her blood was sent to a laboratory, and the pathologist reported that the case was one of malaria. Three days later her physician put in a needle, and drew a quart of pus out of the peritoneal cavity.

Dr. M. ALLEN STARR said that, as the result of his observations, he did not think there was any necessary relation between neurasthenia and the presence of uric acid in the urine. A couple of glasses of sherry, or too free indulgence in a meat, acid, or tomato diet, will produce an excess of uric acid, but there may be no increase in the neurasthenic symptoms. Any intestinal indigestion will, however, cause a decided aggravation, and be shown by the appearance of indicans in the urine.

As regards the use of the Röntgen ray for diagnostic purposes, Dr. Starr said he knew of three cases of tumor of the brain where the Röntgen ray had been employed and had not given any indication of the presence of the growth.

Dr. PEABODY said that his experience coincided with that of Dr. Thompson in regard to the late occurrence of the Widal reaction in many cases of typhoid fever. We usually cannot expect it until the end of the third week, and hence it is worthless as a means of early diagnosis. As to stomach reactions, we can state that the persistent absence of hydrochloric acid in the stomach contents is corroborative evidence of carcinoma, while its persistent presence is corroborative of the absence of carcinoma.

The reliance that is placed by many physicians upon the results of laboratory tests is often to the detriment of the patient. He knew of cases of undoubted malaria, where the patient was allowed to have chill after chill,

quinine being withheld until the report of the pathologist was received.

Dr. Peabody asked Dr. Biggs how much importance should be placed upon the persistence of the Klebs-Loeffler bacillus in the mouth of a patient who has had diphtheria, but who has been perfectly well for two or three weeks. It is known that the bacillus may persist in the mouth for many months.

Dr. Biggs replied that this question had been discussed by the members of the Health Department several years ago, and it was decided that the matter of isolating patients living in a private house after the bacillus had persisted in the throat for a certain length of time should be left entirely with the attending physician, with the proviso that the family should be informed of the possibility of infection, and that the patient should not be permitted to come in contact with children. In the case of children, however, it was decided that they should not be permitted to attend a school of any kind as long as bacilli persisted in the throat. There is no possible question that these cases are dangerous sources of infection, and that the severest types of diphtheria may originate from them.

Dr. Robinson said that in blood examinations he considered it important to have the specimens in a certain case examined by the same pathologist, as each one follows a certain technique which probably causes an appreciable difference in the result obtained

SOUTHERN SURGICAL AND GYNECOLOGICAL SOCIETY.

Proceedings of the Fourteenth Annual Meeting, Held in Richmond, Virginia, November 12, 13, and 14, 1901.

First Day, November 12—Morning Session.

The Association met in the Robert E. Lee Hall on Broad Street, under the Presidency of Dr. Manning Simons of Charleston, S. C.

A short but eloquent address of welcome was delivered by Hon. Eppa Hunton, a distinguished member of the Constitutional Convention, which was responded to by President Simons.

After a brief report from the Chairman of the Committee of Arrangements, Dr. Johnston, the reading of papers was proceeded with.

Laceration of Cervix.—Dr. E. S. Lewis of New Orleans, La., read a paper entitled "Laceration of the Cervix and Its Consequences." He said that lacerations of the cervix were productive of more functional and organic disturbances than had heretofore been supposed. Emmet was the first to draw attention to the more frequent occurrence of cancer upon a lacerated than upon a multiparous cervix. The fascination of abdominal surgery, the brilliant results achieved, and the increasing scope of this work had, in a measure, diverted attention from these minor injuries, which, when neglected, proved most serious, and had an important bearing upon the health, happiness, and life of women. It was not the author's intention to add anything to the literature of this subject, but simply to awaken attention to the importance of the topic which had, in a measure, been lost sight of, and to emphasize what had been so emphatically and graphically described by Emmet. Lacerations of the cervix were of frequent occurrence. There was no question as to the course to be pursued by the accoucheur in lacerations of the perineum, although of less significance than tears of the cervix, as to final results. The different forms of cervical lacerations were described. In moderately recent cases, the classical Emmet operation could not be improved upon; yet, in certain long-standing cases, where the cervix had become thickened enormously from hyperplasia, the Emmet operation would fail to afford relief. In such cases he had used the Schroeder operation, or a modification of it, with gratifying results.

Vaginal Puncture or Incisions for Puriform Disease or Exploratory Purposes are Unsurgical Procedures.—Dr. Joseph Price of Philadelphia, Pa., read a paper with this title. He said the members were familiar with the results of an ideal and complete suprapubic procedure. He had been asked frequently during the past year to see and re-operate on patients upon whom vaginal incisions or puncture methods had been practised. In three very recent operations for the removal of pelvic contents, puncture and vaginal incisions complicated the sections that would have been otherwise comparatively easy. The vaginal fixation, closure of the openings, refilling of puriform or serous sacs, were only local complications; the general condition of the patient became rapidly unfavorable for favorable abdominal work. He was satisfied that the ancient methods of evacuating puriform accumulations, that of cautery or caustics, was much more scientific than the present methods of vaginal incision. Operators, who practised vaginal incisions, never know the precise pathological conditions; they puncture or incise a puriform accumulation and guess at a name, ovarian abscess, pus tube, or pelvic abscess; if the fluid evacuated was serous in nature, they called it encysted serous effusion. The probabilities were that it was a dropsy of the tube or hydrosalpinx. Puriform tubes, as large and tortuous as one's flexed thumb, should never be overlooked or punctured, in his estimation. The error of puncturing an ovarian abscess, or small dermoid—two conditions very commonly found, and both easily enucleated—should never be made. He had never known a patient cured by the methods referred to. The general condition of patients, the rapid restoration to health following clean extirpations from either above or below, were striking when compared with the patients traveling around, seeking relief and health, after the timid, incomplete procedures under discussion.

Dr. Geo. H. Noble of Atlanta, Ga., stated, as a contrast to the experience of the essayist, that he had treated six cases by vaginal incision and drainage, with very good results, but favored operating through the abdomen, and doing more complete procedures where the condition of patients permitted.

Dr. Rufus B. Hall of Cincinnati, Ohio, said he had practised vaginal puncture and drainage in cases in which it was not prudent to do more radical operations on account of the condition of the patients. He had always emphasized the fact to both patients and friends that this operation was not done for curative purposes; that it was a makeshift, and that a more radical operation by the abdomen would have to be done later to afford permanent relief. It was his experience that a large majority of such women returned for radical operations, sooner or later.

Dr. W. D. Haggard, Jr., of Nashville, Tenn., said there were patients who completely recovered from vaginal incision and drainage, and cited an interesting case in point. He fully expected to do an abdominal section in this case to remove a diseased tube and ovary, but apparently the disease had expended its course.

Dr. Lewis S. McMurtry of Louisville, Ky., spoke of the great change that professional opinion had undergone in late years in regard to the operative treatment of pus in the pelvis in women. He referred to the early history of the vaginal operation and its great popularity for years; but, now, French and German surgeons were resorting to the suprapubic route in dealing with puriform collections in the pelvis. These operators were compelled to adopt this route, as their patients only partially recovered from vaginal incision and drainage.

Dr. Edwin Ricketts of Cincinnati, Ohio, did vaginal puncture in a case in 1886. After her first delivery, the woman had a severe pelvic inflammation with pus, and her condition was such as to contraindicate an abdominal operation. She recovered and subsequently bore four

children. When patients did not get well from vaginal puncture and drainage, the abdomen should be opened, and the diseased appendages removed.

Dr. GEORGE S. BROWN of Birmingham, Alabama, held that vaginal puncture and drainage in some cases should be practised as a life-saving measure. He mentioned six cases that he had in the last four or five years in young or recently married women of gonorrhœal infection of the tubes. In these he resorted to vaginal puncture; most of the patients were treated as emergency cases, and, so far as he knew, only two or three of them had been re-operated.

Dr. PRICE, in closing, said he had practically abandoned vaginal puncture and drainage in the class of cases referred to in the discussion, as it was not only a blind, but an incomplete, procedure.

First Day—Afternoon Session.

Treatment of Pelvic and Abdominal Tumors Complicating Pregnancy, with Report of Cases.—Dr. RUFUS B. HALL of Cincinnati, Ohio, read a paper with this title in which he reported four cases. The conclusions arrived at from the cases narrated may be summarized briefly as follows:

In the very small percentage of cases, in which malignant tumors are the cause of the obstruction, they should be dealt with according to the well-established principles of modern surgery. The operation should be made at once without any reference to the child, if, by so doing, there is any additional chance of saving the life of the mother. If the ovarian tumor is thin-walled, of large size, and rapid growth, and the patient is not near her full term of gestation, an operation should be advised, even if the uterus is below the tumor. If the tumor is thick-walled and of slow growth, is not causing much, if any, inconvenience, and rides above the enlarged uterus, an operation is not urgently demanded. If the tumor is small in size, is situated below the uterus, and is fixed either by adhesions or impaction, an immediate operation is demanded. Tapping the tumor for temporary relief should not be done. In fibroid tumors of the uterus, associated with pregnancy, where there are but one or two large nodules, and they are located in the upper half of the uterus, an operation should be advised only in rare instances. These patients can be delivered safely and be operated later, if necessary. If the tumor is below the pregnant uterus and a large nodule blocks up the passage, an operation should be advised and made early. Myomectomy is usually not to be considered in these cases on account of the increased blood supply. The writer would advise it only when an exceptionally favorable tumor for this method is encountered.

Dr. VIRGIL O. HARDIN of Atlanta said he had had some experience with the tumors described complicating pregnancy, and that his conclusions were essentially the same as those enunciated by the essayist. He mentioned two cases of ovarian tumor complicating pregnancy, in which he thought it advisable to operate. These cases were singularly alike; both were primiparæ, and operated during the fourth month of pregnancy. The tumors were removed; the woman recovered, went to full term, and the children are living. He had seen many cases of fibroid tumors complicating pregnancy; but where the fibroid is so situated as to exert no pressure upon the uterus and thereby not to interfere with pregnancy, he thought there was no indication for operation in such cases until pregnancy had been completed.

Dr. GEO. H. NOBLE of Atlanta said his observations were practically the same as those that had been given. The removal of a fibroid tumor complicating pregnancy should be based upon mechanical obstruction to labor. Ordinarily, of course, there were exceptions, as a twisted pedicle, inflammatory conditions, etc.; then the tumor should be removed. If the tumor or tumors were in the lower segment of the pelvis in advance of the fœtus, it was necessary to remove them, or the uterus must be evacuated; and as these tumors can be removed with considerable safety and with a chance of saving the life of the child, it was a feasible operation. Dr. Noble narrated cases in point.

Dr. W. D. HAGGARD of Nashville cited a case which he saw with Dr. Fort, in which a myomectomy was done. The patient was a colored woman, who had been married ten years, and was sterile. She was three and a half months advanced in pregnancy, and had two subserous fibroid tumors—one about the size of an orange on the right side, on the anterior face of the uterus, the other one about the size of a baby's head on the left side, and near the fundus. Both tumors were removed easily without any deleterious effects; the woman was subsequently delivered of a full-grown, living child.

Dr. HALL, in closing, said there were some cases of fibroid tumors complicating pregnancy; also ovarian tumors, that had better not be operated during gestation for the reasons given in this paper. The case mentioned by Dr. Haggard was a favorable one for myomectomy.

A Unique Case of Extrauterine Pregnancy.—Dr. H. TUHOLSKE of St. Louis, Mo., contributed a paper with this title, which was read by Dr. Jonas in the absence of the author. The following is a résumé of the case: Tubal pregnancy (ampullar) of the right side. Tubal abortion with complete extrusion of the gestation sac, unruptured and containing fœtus; hemorrhage and position carried the sac up to the diaphragm between the right lobe of the liver and upper end of the kidney. Implantation of the parietal peritoneum of the diaphragm as far forward as the attachment of the coronary ligament, and in the liver from its upper border to the transverse fissure, down the diaphragm posteriorly and in the upper end of the kidney. Establishment of placental connections, allowing the development of a well-grown living child, and pushing the liver in its growth toward the left and turning it upon its axis, with the coronary ligament as a fixed point, until the right margin of the liver becomes the anterior. Histological examination showed original implantation in the ampulla of the right tube, and the formation of a placenta by efficient transformation of the peritoneum and the liver tissue adjacent. The diagnosis of the case from its history was confirmed by clinical, operative, pathological, and histological evidence.

The Surgical Treatment of Painful Menstruation.—Dr. HENRY D. FRY of Washington, D. C., in this paper stated that pain should not occur at the menstrual period in a healthy woman with healthy pelvic organs. This dual relation between the general health and the generative organs must be constantly kept in mind. One or the other may be at fault, or the trouble may be with both in the same cases. In such cases as demand both medical and surgical care, it is important not to overlook the former. The concentration of attention too closely to the surgical aspect of the case is often the cause of failure to give relief. Surgical treatment carries with it the need of making an examination of the pelvic organs. As these sufferers are nearly always young girls or unmarried women, the indications must be clearly manifest. The character and severity of the pain, its duration and the condition of the patient during the intermenstrual period, must be considered. What results can be expected from surgical treatment? In the discussion of this subject before the last meeting of the American Gynecological Society, the reflected opinions presented a gloomy picture for the woman. His object in presenting this paper is to protest against that verdict rather than offer any original method His experience has been just the opposite. Failure to give relief has been due, as a rule, to some complication, the removal of which subsequently resulted in cure. The line of treatment followed with such satisfactory results is that pointed out in the main by Gill

Wylie: First, thorough dilatation of the cervical canal; then the endometrium is gone over carefully with the sharp curette; irrigation, and often a second curettage; the application of pure carbolic acid; irrigation and dilatation repeated, if necessary. A Wylie drainage plug as large as will readily pass is inserted into the cervical canal, and kept in position by a Smith pessary. For a number of years he was accustomed to leave the plug *in situ* six days, but following the suggestion of Wylie, he now allows it to remain from three to six weeks. He usually keeps the patient in bed two or three weeks after the operation, and if no discomfort be experienced, permits her to get up and go around wearing the plug several weeks longer. He believes the use of the hard-rubber plug does much to aid in the permanency of the relief obtained. It causes the formation of a cicatricial ring of tissue at the point of constriction which insures patulency. He had not seen any bad results follow its use. In a few cases it causes pain, and on that account must be removed sooner than the time mentioned. He attributes the failure of those who deplore their results to the omission of some important point in the technique of the operation. For instance, they simply dilate the cervix, or dilate and curette. Another cause of failure is the unfortunate division and subdivision of the disease into varieties; each variety being described with its appropriate method of treatment. The desire to avoid empiricism has made the subject complex and unpractical.

For all necessary purposes, dysmenorrhœa can be divided into two classes—simple and complicated. The simple, comprises about 80 per cent. of the cases, and the treatment described cures or greatly relieves three out of every four.

The conditions usually found on examination are as follows: The external genitalia are undeveloped; the vagina, cervix, and uterus are small. There is stenosis of the cervical canal and endometritis. The uterus is normal in position or one of exaggerated anteflexion; it is movable and the appendages are healthy. The accompanying endometritis is chronic and due to deficient drainage of the cervix uteri in consequence of stenosis of the cervical canal. The undeveloped condition of the generative organs in young women is very common and parallel to deficient growth of the mammary gland, and its consequent failure to perform the function of lactation.

The second class comprises the cases in which some complication exists. It may be displacement, small fibroids in the body of the uterus, or disease of the tube or ovaries. These complications must be recognized and corrected. In a very small proportion of cases, as in cirrhotic ovaries, operators are driven to produce the menopause artificially. In such cases he believes it advisable to amputate the uterus at the same time, as the subsequent reflex nervous symptoms are diminished and the period of suffering shortened.

Repair of a Complete Laceration of the Perineum in a Girl of Nine Years.—Dr. H. A. Royster of Raleigh, N. C., reported this case. The laceration was produced by the finger of the obstetrician at the patient's birth. The patient was a well-nourished girl of nine years. At her birth, her perineum was torn completely through the recto-vaginal septum, and the explanation of this occurrence is stated to be as follows: the child's grandfather, a very aged physician, acted as accoucheur. Owing probably to dimmed eyesight and infirmity, a breech presentation was evidently mistaken for a vertex position, and the obstetrician, introducing his finger into what he thought was the child's mouth, but which was really its vagina, exerted traction, and the result was a complete laceration of the baby's perineum. No immediate harm came from the accident, and it was resolved not to attempt a restoration of the injured region until the girl was considerably older. During the fall of 1900, she came first under the observation of Dr. Hubert Haywood, who related the above facts, and kindly referred the patient to the speaker for operation.

The parts on examination showed a quantity of dense scar tissue. The tear extended into the vagina to the depth of a half-inch, and the sphincter-ends were plainly seen on either side. No incontinence of fæces had occurred. On November 15, 1900, under chloroform anæsthesia, a butterfly-shaped denudation was made in the vagina, and the exposed edges of the rectum pared, taking pains to dissect out the torn sphincters. The rectal tear was then united with catgut sutures, which were tied inside the bowel and cut short. Silkworm gut was used for closing the vaginal surfaces and bringing together the ends of the sphincter muscle. Perfect apposition was obtained, and rigid asepsis observed in all the details of the technique. In spite of these precautions only partial success resulted, due to the fact that the patient's bowels became unmanageable just at the beginning of the operation, and the denuded area was constantly and unavoidably bathed by a stream of fæces. This unlooked-for disaster was brought about by faulty preparation of the patient before admission. A purgative had been administered the day before, and on the morning of the operation an enema was given, with the report that the bowels had been thoroughly emptied. The continual discharges were a source of much annoyance, but having begun it was considered best to complete the operation. At the end of two weeks it was found that the external sutures did not hold, although union of the upper part of the denuded tissue was secured.

A second operation was attempted April 18, 1901. The same method of procedure was employed, but modified to suit the changed relations. The child was prepared under direct personal supervision, and no fecal contamination occurred. The parts healed promptly, and the result was perfect.

The author could find no parallel to this case in the literature of the subject.

Second Day, November 13—Morning Session

Dr. E. G. Williams of Richmond, Va., reported a case of aneurysm of the abdominal aorta, which was treated by injections of a solution of gelatin into the intracellular tissue with marked beneficial results.

Closure of the Abdominal Incision, with Remarks Upon the Cause and Treatment of Ventral Hernia.—Dr. I. S. Stone of Washington, D. C., read this paper. Ventral hernia following abdominal operations is generally due to wound infection and suppuration, with loss of fat and cellular tissue. Hernia may, however, result from imperfect wound coaptation, or may be a result of some accident after operation. It is not infrequently due to enteroptosis, which may prove an obstacle to success and may defeat all attempts at relief, however well planned. In all ventral hernias the skin and peritoneum will be found united, a condition which doubtless began soon after the wound was closed. Wound infection will usually result in suppuration with loss of tissue, which leaves a space between the parts, and also permits the sutures to become loosened. This space is filled with granulation tissue as healing progresses, but an important change has already occurred, namely, the peritoneum and skin are nearer together than before, and the separation of the muscle and fascia has, perhaps, allowed the entrance of a wedge of peritoneum to enter and to separate still farther the walls of the wound. It is easily seen that in this way a ventral hernia is practically assured before the wound has entirely healed, or, at least, before firm union has taken place. In fat subjects, the greater liability of wound infection increases the danger of hernia, and in these we have the additional factor of greater intra-abdominal pressure. The author has had excellent results with both buried and through and through transfixion sutures. He prefers the latter because the material

is sterilized with more certainty, and the closure requires less time. He prefers to make the incision in or near the median line, but does not avoid the muscle, but divides the fibers directly down to the peritoneum.

One of the precautions taken by the writer is to excise the long flap of peritoneum before placing the sutures. This excessively long flap is not well nourished, and, if allowed to remain, favors a collection of blood or serum between it and the muscle in front. In any wound of from three to six inches in length, a strip of peritoneum of one or two inches in width may be removed with advantage. This disposes of that portion of the peritoneum which has been overstretched during the operation, which has possibly been infected, and which is not well nourished. The removal of the flap permits a perfect edge-to-edge coaptation and prevents, to some extent, the wedge of peritoneum, which is the beginning of a ventral hernia.

My First Abdominal Section.—Dr. THAD. A. REAMY of Cincinnati, Ohio, read a paper with this title. The operation was done in February, 1864, at the patient's house. She was sixty years of age; married, the mother of three children. The cyst removed proved to be multilocular, weighing with contents forty-six pounds. The incision was made in the median line, and was five inches in length. Adhesions to the parietal peritoneum were extensive and at many points comparatively firm. On their separation, which was done by the fingers, sponge, and handle of a scalpel, considerable and persistent hemorrhage supervened. Before attempting to deliver the tumor, it was tapped with an ordinary trocar, patient turned upon her side to deliver the fluid into a vessel. The pedicle was ligated *en masse* by a heavy cord of shoemaker's thread (not silk). One interesting feature was the manner in which hemorrhage was controlled in this case. Regarding this point, Dr. Reamy says: "The weather was cold, with an abundance of clean snow on the ground. I ordered some brought in. Compressing it with my hands into firm balls, it was held against the bleeding surfaces. The bottom of the pelvic cavity soon contained quantities of water from the melting snow, mixed with blood. This was sponged out and the compression with snowballs continued. In a comparatively short time, to my delight, the hemorrhage ceased; when I dried the cavity with sponges, and closed, without drainage, except what could be secured by the ligature already referred to, which was left protruding from the lower angle of the abdominal incision. The abdominal incision was closed by through-and-through sutures of the same material and size as that used for ligating the pedicle." Patient made an excellent recovery.

Dr. REAMY then briefly compared some of his more recent work with his earlier work, and said that the results have certainly not been better than those secured by other operators equally favorably situated. In his last series of one hundred cases of abdominal section for all causes, the mortality was 6 per cent. In the preceding one hundred cases the mortality was 8 per cent., three of these being bad pus cases. In the series of one hundred cases preceding this, the mortality was 9 per cent. Excluding other conditions and selecting only cases of simple and compound ovarian tumors, out of three hundred cases above quoted, the mortality is but 2 per cent. In making his estimate of the value of the above experience, he desired to state that within the last six years more than ever before he had selected his cases. He declines operation on cases of far-advanced malignant disease of the uterus where others will operate.

The whole number of abdominal sections made by him within the thirty-seven years intervening since the case reported is 1,600. This does not include 204 vaginal hysterectomies done by him, with six deaths, and 198 recoveries from operations.

Some of the Avoidable Causes for Disaster in Appendicitis Work.—Dr. ROBERT T. MORRIS of New York City read a paper on this subject. Among other things, the author said: "If we step out upon the street and get ten healthy policemen, and put half a yard of gauze into their abdominal cavities to-day, we shall find at the end of a week that 'we did not get them in time.' That is an excuse which is so often offered when we try to make a weak and poisoned appendicitis patient bear what strong men cannot bear. If, in addition to the mechanical insult offered by gauze packing, we add the chemical insult of iodoform, we should have still fewer of these policemen in time. They would have, what most house surgeons call, septicæmia. The differential diagnosis between septicæmia and dangerous iodoform poisoning is difficult to make, excepting on the objective evidence offered by the presence of iodoform in the wound, the presence of free iodine in the urine, and a wound of healthy appearance while the patient is failing. In insidious iodoform poisoning the wound looks well, while the patient does not. In septicæmia neither the wound nor the patient looks well. That is a constant diagnostic difference. Gauze packing shocks the patient, lessens his natural resistance, and consequently interferes with his manufacture of phagocytes. Treatment of to-day should avoid interference with the patient's ability to furnish abundant leucocytes. Accessible statistics show us that we do not need to employ gauze packing in our appendicitis work.

Extensive and multiple incisions lessen the patient's ability to furnish leucocytes for the occasion, when all of his natural protective powers need to be respected by the surgeon. A beginner needs a great deal of room at the patient's expense, but it is in the interest of the patient to work chiefly by the sense of touch through small incisions. In other words, to come as nearly as possible to letting the patient alone. Another approach toward the idea of letting the patient alone consists in rapid work, without much exposure or handling of bowel. Almost any appendicitis operation, no matter what the complications, should be completed in from fifteen to thirty minutes. Many a patient who is holding finely to his natural resistance at the end of fifteen minutes has lost it at the end of forty-five minutes. The idea that the surgeon must get all of the pus out of the peritoneal cavity is out of date. The leucocytes will attend to the matter more effectually. The principle is this: the bacteria and the leucocytes are at warfare with each other in any case of infection. The leucocytes may be almost on the point of winning, but not quite. If we step in and help the leucocytes by removing most of the pus, with its army of bacteria and toxins, the balance of power is transferred to the phagocytes, and they are competent to care for the case, as a rule, if the surgeon himself has not disabled the patient's resistance. It is a constant surprise to see how well appendicitis patients recover, and without post-operative complications, if we make the way easy for them. The best way, of course, to avoid disaster is for the surgeon to do the operation before the bacteria have operated very much. Physicians sometimes overlook the fact that the patient is undergoing an operation all the while that bacteria are at work upon the appendix, so that it really comes to be a question as to who shall be allowed to operate in the case, the bacteria or the surgeon."

President's Address.—This was delivered by Dr. MANNING SIMONS of Charleston, South Carolina. Attention was directed to the deaths of Drs. Hunter McGuire of Richmond and W. D. Haggard of Nashville, both founders of the association, who had died during the year. These gentlemen were eminent in their profession, honorable and upright in their private lives, and their death is an irreparable loss to the association.

Speaking of medical societies, the President stated that they are the natural outcome of the development of the science and art of medicine and surgery, and for this reason they have multiplied in recent years to fulfill the purpose of discussing propositions bearing on the pro-

motion of more systematic observation and plans of operation, and of greater uniformity in the mode of publishing results, as well as for the consideration of matters on which the co-operation of corresponding societies is desired. To the wonderful development of medicine and surgery during the nineteenth century may be traced the increase of such organizations. Private scientific societies have originated chiefly during the past century, the demand for their existence being due to the necessity of increased organization of rapidly developing knowledge, and the desire among workers for a common ground to meet, discuss, and compare results, and collect facts for future generalization.

There has been a general demand for specialists in every department of life in recent years, and in medicine and surgery particularly has this demand been evident both in the profession and among the laity. Patients now demand and require special treatment of their ailments, and this requirement has been met by the division of medicine and surgery into many departments. As usual, in the development of a new idea, there is a tendency to go to extremes, and we now find even the recognized specialties undergoing subdivision in accordance with the trend of individual inclination. It is probably admitted that general knowledge is the aggregate of special knowledge, but conversely in lividual special knowledge is attained at the expense of general information.

Accurate diagnosis naturally forms the basis upon which successful operative work must rest, and it must be admitted that skilful diagnosis depends upon extensive general knowledge. Acuteness in diagnosis is the result of general learning and familiarity with all the elements conducive to a true appreciation of symptomatology and pathology.

With reference to qualifications, the speaker said that there should be some provision of a like kind for special examinations to determine the qualifications of those who desire to enter upon the practice of a specialty, and particularly that of surgery and gynecology. In these days of materialism, it would seem out of season to speak of the sentimental aspect of medicine; but medicine has certainly had its sentimental side.

The times have changed, and physicians have changed with the times. The demands of modern medicine have to a large extent divested the practice of sentiment that formerly surrounded it. It is a question how far that degree specialism has led physicians into the paths and methods of ordinary business.

Dr. SIMONS then discussed the relations of the patient to the doctor, and those of the doctor to the patient, saying that they had changed in conformity to the modernized methods of practice.

In conclusion, he expressed his appreciation of the honor conferred upon him in having elevated him to the office of President of the Association.

(To be continued.)

Camphor Eating.—It is surprising, says the *Indian Medical Record*, to note what a number of camphor-eaters there are among the well-to-do classes. The idea seems to prevail that this gum, taken in small and regular doses, gives a peculiar clear creaminess of complexion, and scores of young women buy it for this purpose. The habit is, moreover, very difficult to cast off, for camphor produces a mild form of exhilaration and stupefaction; and in many instances, where very large doses have been swallowed, the habit has become a sort of slavery. These camphor-eaters all have a dreamy, dazed, and very listless air, and in most of them there is an ever-present longing to lie down, or at least, to rest. Extreme weakness generally follows the taking of regular doses, and cases have been seen where it has been almost difficult to tell the effects from those of alcohol. As to the complexion, if a ghastly pallor be an improvement, camphor certainly produces it.

New Instruments.

A NEW OPERATING TABLE.

By W. J. LEFEVRE, M.D.,
CLEVELAND, OHIO.

THE table illustrated was designed especially for rectal examinations. By placing the patient on his side, in the Sims' position, with the table flat, as shown in figure 1, and then adjusting the side-shelf, as shown

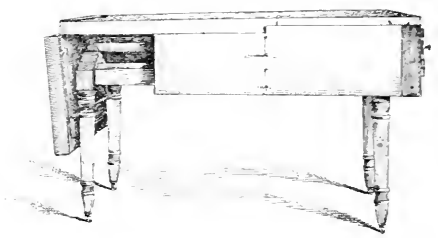

FIG. 1.

in figure 2, he can readily be changed to practically a knee-chest posture. The position is quite comfortable for the patient, and the table is easily manipulated by the operator, being so balanced that the weight of the patient holds it up. The table is 4 feet long, 2 feet wide, 31 inches high, with an extension shelf on one end 14 feet long. The side-shelf is 10 inches wide, and so hinged that it will fold upon itself, and then fold under the edge of the table, when

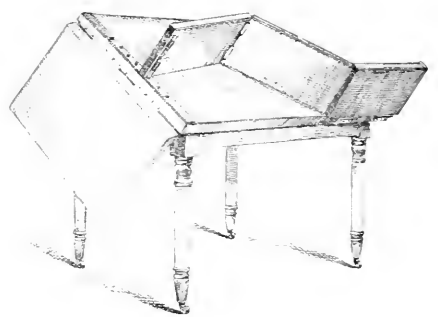

FIG. 2.

down. When up, it is held by a slip bolt at each end, the head one being adjustable, as shown in figure 2. The top is hinged 11 inches from the shelf side, and tilts to an angle of 90°. The top locks down with an elbow catch, and, when up, is held securely by a hinge piece on the high side. The table can be made right or left, as desired.

Cure of Poisonous Snake Bite.—A cure of this description was recorded in the London *Times* a short time ago by a correspondent, who explains that the medical man in India, having been called to see a coolie woman who had been bitten by a large snake, supposed to be a cobra, injected a full dose of Dr. Calmette's antivenene, but was not sanguine as to the result, the patient's condition being apparently hopeless. The effect of the remedy was marvelous. Consciousness returned in fifteen minutes, and he was so encouraged by the result of the first injection that he decided to give another dose of the serum. It acted like magic, and within three hours of the first injection the patient was well. The operator is satisfied that even in desperate cases Dr. Calmette's serum is a reliable remedy for the bites of poisonous snakes.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 16, 1901:

	Cases.	Deaths
Measles	277	8
Diphtheria and croup	269	37
Scarlet fever	183	13
Smallpox	8	3
Chickenpox	19	..
Tuberculosis	219	150
Typhoid fever	89	18
Cerebrospinal meningitis	..	2

Viability of the Bacillus Pestis.—The conclusions arrived at as the result of investigations into, and experiments with regard to, the above subject, undertaken by the direction of Passed Assistant Surgeon M. J. Rosenau, director of the hygienic laboratory of the Marine Hospital Service, are as follows:

1. The bacillus pestis is not a frail organism. It resembles the hemorrhagic septicæmic group or the coccobacilli, as far as its viability is concerned.

2. Temperature is the most important factor in the viability of the plague bacillus. It keeps alive in the cold, under 190° C., a very long time. It dies quickly, especially when dried, at the body temperature, 37° C.

3. Moisture favors the life of the bacillus pestis. It usually dies in a few days when dry, even in the presence of albuminous matter, provided the temperature is above 30° C. It may keep alive and virulent when dry for months in the cold, under 19° C.

4. Sunlight kills the organism within a few hours, provided the sun shines directly upon the organism and the temperature in the sun is over 30° C. The effect of sunlight is not very penetrating.

5. The virulence of the bacillus pestis is often lost before its vegetability.

6. It is unlikely that new dry merchandise would carry the infection. The organism usually dies in a few days on the surface of objects such as wood, sawdust, bone, paper, etc.

7. Clothing and bedding can harbor the infection for a long time and may act as fomites. The bacillus lives for months, when dry, in albuminous media at temperatures under 20° C.

8. Food products may carry the infection of plague. The bacillus lives a long time in milk, cheese, and butter. It usually dies quickly on the surface of fruits and prepared foods.

9. The organism may live a long time in water, although plague is not a water-borne disease.

10. The plague bacillus does not live long on paper, and first-class mail is therefore not apt to convey the infection.

11. The colder the climate, the greater the danger of conveying the infection on fomites—clothing, bedding, food, merchandise, etc.—and more extensive disinfection is required in such a climate in combating the disease than in tropical regions.

12. The plague bacillus is destroyed by sulphur fumigation and by formaldehyde gas in the strengths in which these disinfectants are usually employed. The gases can only be depended upon as surface disinfectants. In disinfecting ships, warehouses, dwellings, and other places infested with rats, fleas, and vermin, sulphur is better than formaldehyde, because formaldehyde gas fails to kill the higher forms of animal life.

13. A temperature of 70° C. continued a short time is invariably fatal for the plague bacillus. The ordinary antiseptics are all efficacious in their usual strength for non-spore-bearing organisms. Efficient surface disinfection may be accomplished by exposing objects to the direct sunshine on warm days. The temperature in the sun must be above 30° C.

Suicide in France.—The number of suicides for 1898 showed as light increase, namely, 9,438, as against 9,356 in 1897, or an increase of 82. The figures for a period of five years before, and including 1898, were as follows: 1894, 9,703; 1895, 9,263; 1897, 9,356; and 1898, 9,438. It seems fair to conclude from these figures that the diminution which began in 1895 was the commencement of a real diminution, and not merely of a temporary one. The Department of the Seine supplied one-sixth of the total number of the suicides in 1898, namely, 1,566, or 64 less than in 1897. Of the persons committing suicide, 85 were under sixteen years of age, 477 were between sixteen and twenty-one years of age, 1,436 were between twenty-one and thirty years of age, 1,285 were between thirty and forty years of age, 1,669 were between forty and fifty years of age, 1,882 were between fifty and sixty years of age, 2,356 more than sixty, and the ages of 278 were unknown. The civil condition of those committing suicide was ascertained only in 8,809 cases. The unmarried numbered 3,008, the married with children 2,502, the married without children 1,422, widows with children 1,113, and widows without children 834. As to employment, 2,436 cases occurred among agriculturists, 1,668 among those employed in various industries, 1,262 among business men and merchants, 1,380 among professional men, 1,511 among domestic servants, and 1,181 among those not in employment or whose employment could not be ascertained. As to motive, 1,537 suicides were set down to poverty and reverses of fortune, 943 to family troubles, 624 to love or jealousy, 1,226 to drink, 2,705 to various troubles (of which physical pain accounted for 1,785), 1,347 to cerebral disease, and in 1,056 the cause remained unknown.—Paris Correspondent to *Lancet*.

Virchow as a Politician.—The *London Spectator* says: "Berlin has been honoring itself by celebrating the eightieth birthday of Professor Virchow, the great pathologist, whose demonstration that the human anatomy was based on cells laid the foundation of modern medicine. He is the son of a little farmer in Pomerania, and his rise from that position to the headship of science in Germany has been marked by a singular peculiarity. Professor Virchow, though devoted to scientific research, has been a weighty politician. He was practically for twenty-five years the leader of the Liberal party, had once the honor of a challenge from Bismarck, and incurred the fiercest anger of the Court, which secured his expulsion from his scientific appointments. He was also a hard worker in the field of local government, having been for forty years a member of the Municipal Council of Berlin, which he induced to undertake and carry through great sanitary reforms. He is now honored by Court and people alike, the Emperor forwarding to him the Grand Gold Medal for Science in a letter, which, though without warmth, acknowledges to the full his scientific rank, and the people complaining that the decoration is insufficient. Here rarely or never do our scientific men or even physicians enter politics."

Entries at British Medical Schools.—The *British Medical Journal*, October 19, says: "We have received returns of some of the medical schools, but as others have not replied to our inquiries, it is not possible to publish a full list of the number of new students at the several schools. We learn, however, that a number of new students who have entered for the full curriculum at the schools in London is as follows: St. Bartholomew's, 84; Charing Cross, 14; Guy's, 68; King's College, 25; London, 64; St. Mary's, 35; Middlesex, 10; St. Thomas, 48. With the exception of St. Thomas, which has one student more, and King's College, which had the same number last year, these returns in each case show a decline as compared

of the corresponding returns made at this time last year. The total for the schools mentioned is for this year 557, as compared with 306 in 1900. The London School of Medicine for Women shows an increase, the number this year being 30, as compared with 22 last year. The returns from the schools in the provinces are also as yet incomplete, the number of students who have entered for the full curriculum is at University of Durham 20, as compared with 25 last year; Bristol University College, 18, as against 13 last year; Owen's College, Manchester, 54, as compared with 47 last year; Yorkshire College, Leeds, 27, as against 38 last year; University College, Sheffield, 12, as against 8 last year; University College, South Wales, Cardiff, 14, as against 10 last year. Total, 151, as against 150 last year.

London Hospital Saturday Fund.—The quarterly meeting of the Board of Delagates of the Metropolitan Hospital Saturday Fund was held on October 5. The report of the Finance Committee showed that the receipts from the workshops, etc., from January to September 14, had amounted to £0,865 ($40,325); as compared with £0,128 ($45,640) at the corresponding period of last year.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 16, 1901:

SMALLPOX—UNITED STATES.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of such receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ATLAS AND PRINCIPLES OF BACTERIOLOGY. By LEHMANN & NEUMANN. 8vo, 511 pages. Part 1 and 2. W. B. Saunders & Co., Philadelphia, Pa. Illustrated. Price, cloth, $5.00 net.

A LABORATORY HANDBOOK OF URINE ANALYSIS AND PHYSIOLOGICAL CHEMISTRY. By CHAS. G. L. WOLF. 8vo, 203 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa., Price, cloth, $1.25 net.

A TEXTBOOK OF PHARMACOLOGY. By TORALD SOLLMANN. 8vo, 892 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price, cloth, $3.75 net.

THE SURGICAL TREATMENT OF DISFIGUREMENTS AND DEFORMITIES OF THE FACE. By J. B. ROBERTS. Second edition. 8vo, 72 pages. Illustrated. The Philadelphia Medical Publishing Co., Philadelphia, Pa.

ON PARALYSIS AGITANS. By R. T. WILLIAMSON, M.D. 8vo, 70 pages. Illustrated. Sherratt & Hughes, Manchester.

DISEASES OF THE INTESTINES. By J. C. HEMMETER. In 2 volumes. Vol. I, 8vo, 742 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia, Pa. Price, $5.00 per vol.

THE ACCESSORY SINUSES OF THE NOSE. By A. LOGAN TURNER. 8vo, 211 pages. Illustrated. William Green & Sons, Edinburgh.

A TEXTBOOK OF MEDICINE. By C. H. FAGGE. 8vo, 1123 pages, Vol. I. P. Blakiston's Son & Co., Philadelphia, Pa.

A TREATISE ON SURGERY BY AMERICAN AUTHORS. By ROSWELL PARK. Third edition. 8vo, 1408 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. Price, cloth, $7.00 net; leather, $8.00 net.

GUIDE DE L'EXAMEN GYNECOLOGIQUE. By Dr. L. LEON-ARCHAMBAULT. 12mo, 116 pages. Illustrated. A. Maloine, Paris. Price, Fr. 3.00.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. By ALBERT H. BUCK. Imperial octavo, 867 pages. Illustrated. Vol. III. William Wood & Co., New York. Price, cloth, $7.00; leather, $8.00; half morocco, $9.00.

A TRAVERS LA MÉDECINE. By H. GUIMBAIL. 8vo, 135 pages. A. Maloine, Paris, France.

LA FAIBLESSE IRRITABLE SEXUELLE. By V. RENZA. 8vo, 112 pages. G. Sauleau, Paris, France. Price, Fr. 2.50.

PUBLIC HEALTH REPORTS. 8vo, 1,689 pages. By SUPERVISING SURGEON-GENERAL M. H. S. Vol. XV, Part I, Nos. 1 to 26. Washington, D. C.

A TEXTBOOK ON DISEASES OF THE EAR, NOSE, AND THROAT. By CHAS. H. BURNETT, M.D. 716 pages. Illustrated. J. B. Lippincott, Philadelphia, Pa.

INFANT-FEEDING IN ITS RELATION TO HEALTH AND DISEASE. By LOUIS FISCHER. Second edition. 8vo, 343 pages. Illustrated. F. A. Davis Company, Philadelphia, Pa.

BATH MATTERS. By PRESTON KING. 8vo, 128 pages. Illustrated. J. W. Arrowsmith, Bristol, England.

THE WISDOM OF PASSION; OR, THE MOTIVES OF HUMAN NATURE. By SALVARONA. 8vo, 248 pages. Mystic River Book Company, Boston, Mass. Price, $2.00.

Quinquaid's Sign of Alcoholism.—The test can be made by placing the patient's fingers so that one is separate from the other, and then firmly rest them across the observer's hand at right angles. For several seconds nothing unusual is noted, then follow slight blows, as if the bones of each finger were thrown back suddenly, one upon the other and struck the palm. The pressure on the observer's hand should be moderate. The crepitations vary from a slight rubbing to a true crackling. Aubry maintains that the sign is pathological and may be present in those who have indulged but little in alcoholics. Sometimes it disappears rapidly, after abstinence in some, but may persist for a long time under similar habits in others. It may be absent in some habitual drinkers.

VAGINAL CANCER.

BY W. ROGER WILLIAMS, F.R.C.S.
CLIFTON, BRISTOL, ENGLAND.

OF the organs evolved from the different segments of the Müllerian ducts, only the uterus manifests great proclivity to tumor formation, for the vagina and Fallopian tubes are seldom affected. Thus of 9,226 tumors in women tabulated by me, 2,648 were of uterine origin (cancer, 1,571; sarcoma, 2; myoma, 1,073, and cystoma, 2), whereas only 54 arose from the vagina (cancer, 40; sarcoma, 2; myoma, 3; and cystoma, 9). From this it may be inferred that the biological peculiarities which determine a given part to tumor formation depend more upon functional than upon genetic considerations. The vagina, for instance, is physiologically more akin to the vulva than to the uterus, and the results of this similarity are apparent in its pathological neoplastic variations.

Although many cases of vaginal cancer have from time to time been reported in Anglo-American publications, yet no work dealing with the *ensemble* of the subject has hitherto appeared in the English language. Notwithstanding its rarity, cancer of the vagina is by far the commonest form of primary vaginal neoplasm. According to Friedl, the medical journals up to 1896 contain records of 130 cases. Five examples of it have come under my own observation. My data, derived from patients under treatment at the chief London hospitals, show that only 4.3 per cent. of all cancers in women are of vaginal origin. Gurlt, from Vienna hospital experience, gives the percentage as 1.6. Of 7,408 female cancer deaths in Hamburg, lately (1900) tabulated by Reiche, only 29 were of the vagina, or .38 per cent.; and of Hecht's 4,507 cases, 50 were vaginal, or 1.1 per cent. Averaging these results, it may be said that less than 1 per cent. of all cancers in women are of vaginal origin.

Those who believe that "irritation" is the chief determining factor in cancer causation will find these figures a stumbling block; for few parts of the body are more prone to all kinds of "irritation" than the vagina. Moreover, although vaginal prolapse and invagination—when irritative conditions may be presumed to attain their maximum—are of common occurrence, yet remarkably few instances of cancer have been noted in this connection (Zizold, Pchelin, etc.). Just so is it with regard to the wearing of pessaries, for only a very few instances of the association of cancer with this habit have been recorded (Meyer, Hegar, etc.), whereas the number of those who have worn these instruments for years is enormous.

Although the record of cases of vaginal cancer generally leaves much to be desired as regards histological details, yet, from cases in which the minute structure of the tumor has been carefully described, it may be gathered that nearly all primary vaginal cancers are of the squamous epithelial, or, as I prefer to call it, the epidermoidal type. Hence it is to the epithelial elements of the vaginal lining membrane and its derivatives that we must look for the origin of vaginal cancer. This structure is commonly described as a "mucosa," but it is rather a skin-like, dermo-papillary formation, lined by stratified, anastomosing, polymorphic-epithelial cells, which are arranged as in the general integument—except that there are no hairs and no glands. Moreover, cornification is defective; and, judging from the extreme rarity of melanotic neoplasms of vaginal origin, there is also a decided deficiency of pigment. Zizold has ascribed the comparative immunity of the vagina, as compared with the cervix uteri, from cancer to the absence of glandular structures. The vaginal membrane is freely supplied with blood-vessels, lymphatics, and nerves. Cavernous spaces and quasi-erectile structures abound in it. Lymph-adenoid structures are also met with, which sometimes take the form of distinct nodules (Dobrowolski). The lubricity of the part appears to be due to the constant deliquescence of its superficial cells, and to exudation from the local lymphatics. A peculiarity of this moisture is its acid reaction, which has been ascribed to the agency of microbes.

Most embryologists describe the vagina as being evolved from the fused posterior extremities of the Müllerian ducts. According to some, however, the Wolffian, as well as the Müllerian ducts, participate in this fusion, which begins at the latter part of the third month, and is completed two months later. The first recognizable rudiment of the vagina consists of a mass of epithelial cells, which, according to Nagel, differ *ab initio* from those whence the uterus is evolved, being shorter, flatter, and less cylindrical. In this cellular mass a cavity is subsequently formed, by absorption of the central cells, canalization being completed by the seventh month. Berry Hart describes the epithelial cells of the lower ends of the Wolffian ducts as forming, by proliferation, during the third month, two swellings—the Wolffian bulbs—which subsequently coalesce. At this time there is no obvious demarkation between uterus and vagina, but early in the fifth month, by the upward extension of Wolffian cells, the rudiments of the portio and the vaginal fornix are sculptured out of the lower part of the Müllerian canal. Similarly, by the downward extension of Wolffian cells, the rudiment for the lower part of the vagina is formed. These Wolffian cells, Hart regards as of epiblastic origin, and thus he explains the skin-like structure of the vaginal membrane, and of the inner layer of the hymen. This hypothesis also explains the occasional presence in the vagina of a congenital transverse septum, of which Konikow has lately reported an instance.

A controversy is still maintained concerning the question of glandular structures in the vaginal membrane. As previously mentioned, most observers have failed to find structures of this kind. Preuschen and others have, however, asserted their existence; while Hennig and Heitzmann have met with epithelial-lined follicles, *culs-de-sac*, and diverticula. Davidsohn, who has recently investigated the subject,

found numerous small cysts, follicles, etc., lined with cylindrical epithelium, which he considers to be aberrant offsets of cervical glands, analogous in origin to the *ovula Nabothii*. These formations were chiefly located in the upper part of the vagina. It is probable that foreign elements of this kind furnish the germs, whence cylinder-celled glandular cancers of the vagina arise, of which instances have been reported. Wolffian and Müllerian "nests," which are of common occurrence in the vaginal walls, may also play a part in the histogenesis of vaginal cancer. In the development of papillated structures, like the vaginal membrane and the cutis, the epidermoidal cells play an important part. Processes of their proliferous cells, growing into the subjacent stratum, cause these structures to arise. Fragments of these processes, detached during the course of development, are the germs of the "epithelial pearls" met with in and beneath the vaginal corium. The chief morphological feature that marks the transformation of simple epithelial hyperplasia into epithelial cancer consists essentially in an indefinitely sustained, modified, superinduced repetition of the above process, affecting at first but a single cell or a small group of such cells. In this way, cancer of the vagina begins by proliferous cells of the interpapillary region of the rete mucosum, or its aberrant extensions, growing into the adjacent stroma. These cells, multiplying and developing in semi-independence, form knobby projections and ingrowing columns. When the new formation does not progress much beyond this initial stage, the ingrowing cells preserve their normal form, and their mutual relations are but little altered; the columns fail to penetrate deeply, and the malady progresses slowly, and dissemination is exceptional. This is the tubular variety.

In the graver and much commoner form of the disease, the departure from the normal is more decided; changes take place in the grouping of the cells, and "nests" are formed; the ingrowing columns become irregularly bulged; they increase rapidly and penetrate deeply, branching and anastomosing, and sooner or later other parts are secondarily affected. This is the lobular variety—the typical form of vaginal cancer. The initial manifestation of vaginal cancer usually takes the form of a small, solitary nodule; but Lange, Schwartz, and others have reported instances of primary multiplicity. Mercantor has met with independent outbreaks of the disease in the vagina and uterus. Most of these multiple manifestations are no doubt due to local dissemination from the primary focus, but it is probable that some of them are due to the spread of the disease by "contact infection." Olshausen has reported an instance of this kind, in which the disease was propagated from the posterior to the anterior vaginal wall.

In most parts of the body in which cancer exists, certain hyperplastic lesions of the epithelia of the locality are commonly found, which in covered parts may eventuate in polypoid formations. In exposed parts—such as the buccal cavity, where the various stages of the process can be followed—lesions of this kind (leucoplasia, ichthyosis, etc.) have often been observed to precede and culminate in cancer. Since these changes are seldom limited to the precise starting point of the cancerous disease, it may be inferred that the biological disturbance of which cancer is the outcome affects also, in a less degree, the epithelia of the vicinity. Several instances of vaginal cancer developing in connection with lesions of this kind have lately been reported (Pichevin and Pettit, Monod, Schwarz, Bex, Reclus, etc.); and in a few cases "kraurosis" has been known to have a similar termination.

Cancer may start from any part of the vaginal walls, but modern statistics show, contrary to the opinion entertained by Cruveilhier, that most cases arise from the posterior wall, especially its upper part.

Thus, of seventy-six cases tabulated by Bernard, fifty arose from the posterior wall, and only fifteen from the anterior; while in nine cases the lateral walls were affected (left in five, and right in four cases), and in two the disease was of the annular variety.

At an early stage, vaginal cancer presents clinically either as a papillary excrescence, a firm elastic nodule, or as an infiltration. "Cauliflower," villous, and vascular, quasi-erectile forms are met with. The stroma sometimes undergoes myxomatous metamorphosis, as in the so-called "colloid" cancers, and in this connection pseudo-cysts may arise (Bernard, Pean, etc.). An excess of myomatous elements has also occasionally been noted in the cancer stroma, as in a case of "myocarcinoma," reported by Körte. An instance of "lymphangioendothelioma cavernosum hæmorrhagicum" has been described by Klien.

As a rule, ulceration, having the usual cancerous characteristics, soon supervenes, with fetid sanious discharge. In advanced cases, owing to local extension, a large part, or indeed the whole, of the vaginal wall may be invaded, and I have seen a remarkable instance in which, besides the vagina, the vulva, uterus, and bladder were thus involved. Sometimes the disease disseminates in the vaginal walls as multiple discrete nodules, of which Fenger has reported an instance.

At first, the malady is limited to the vagina; but after a time it spreads to adjacent structures—bladder, urethra, labia, rectum, etc. Its tendency is to spread forward toward the vulva, rather than backward toward the uterus; so that the latter organ generally escapes, except in advanced cases. Under the title of "Épithélioma liminaire," Pozzi has described a form of cancer which, originating in the vaginal *cul-de-sac*, spreads impartially to the uterus and to the vagina.

Posteriorly evolving cancers tend to spread backward and forward involving the rectum, when pain, tenesmus, constipation, and obstruction may result, with the eventual formation of recto-vaginal fistula. Anteriorly evolving cancers are apt to invade the base of the bladder, and the peri-urethral region. These, at an early stage, cause frequent and painful micturition, dysuria, and later retention, with cystitis and vesico-vaginal fistula in some cases. In this form of the disease, the orifices of the ureters are often more or less involved, hence the proneness to hydronephrosis, pyonephrosis, pyelitis, nephritis, etc.

Cancers of the lower part of the vagina nearly always invade the vulva, so that when seen at a late stage, it may be difficult to determine their precise seat of origin. Pelvic peritonitis is a common complication of vaginal cancer; and from the invasion of the peritoneal pouches by the ulcerating growth general peritonitis may ensue. Hydro-, pyo-, and hæmato-salpinx not infrequently complicate the disease; and collections of this kind—discharging into the peritoneal cavity—may cause fatal peritonitis. Owing to thrombosis of the pelvic veins, consequent on dissemination of the disease in the pelvis and inflammatory complications there, œdema of one or both lower extremities may occasionally be met with. In Bellamy's case, a large mass of inflamed cancerous glands on the left side of the pelvis had occluded the left common iliac vein, and caused acute œdema of the left lower limb, when fatal pyæmia rapidly ensued.

Dissemination of the disease in the adjacent lymph glands generally takes place sooner or later, but it is usually of somewhat tardy development. The vagina is well supplied with lymphatics, although not so

abundantly as the uterus. In the corium and the subjacent connective tissue are numerous fine networks, while the musculature is permeated with anastomosing vessels of large size. These networks freely intercommunicate. Their chief efferent trunks are to be found posteriorly between the vagina and the rectum.

Most of the vaginal lymphatics go to the pelvis, where they enter the glands of the ilio-pelvic group. These present as a chain on each side of the pelvis, which extends from the angle of bifurcation of the common iliac artery above to the upper part of the great sacrosciatic foramen below. According to Poirier, efferent vessels from the upper part of the vagina pass, with the cervical lymphatics, to the lower ganglia of this chain. Those from the middle part of the vagina, following the course of the vaginal arteries, enter the lowest ganglia of the ilio-pelvic chain. These glands are situated over the upper part of the great sacrosciatic foramen, where they come into relation with the lateral part of the rectum, the great sciatic nerve, and the blood vessels derived from the anterior division of the internal iliac. The lymphatics from the lower part of the vagina go, with those of the external genitalia, to the internal group of inguinal glands. In vaginal cancer the inguinal glands are also often involved indirectly, by spread of the disease from the pelvis, along the external iliac blood vessels, etc. Thus the great frequency with which the inguinal glands are involved in vaginal cancer—those of both sides often being implicated—may be accounted for.

Lymph-gland enlargements, secondary to vaginal cancer, are often due to septic infection derived from the primary tumor, and thus we may account for the fact that, when invaded by cancer, these glands relating often suppurate at an early stage. Thus, in Herman's case, the glands of both inguinal regions suppurated; and Brückner found the pelvic glands similarly affected.

As in cancer of the uterus, dissemination of the disease in internal organs and distant parts is not very common. I have, however, met with two instances of this kind, in one of which both lungs, pleura, the liver, and the left kidney were involved; while in the other both lungs and the left kidney were affected, as well as the left Fallopian tube, the pelvic, bronchial, and mediastinal glands. In Herman's above-referred-to case, the right ovary was cancerous, and there were secondary deposits in the liver. Warder has found dissemination in the lungs and liver; and in a patient with recurrent disease involving the vagina, labia, rectum, and inguinal glands. Gill saw numerous disseminative nodules form in the integument of the abdomen. In Curtis' case there were metastases in the bones of the skull. Boissier, Recklinghausen, and others have also reported instances of wide-spread dissemination of the disease.

In vaginal cancer, death generally results—when not determined by some such complications as I have previously mentioned—from asthenia, with progressive general enfeeblement, cachexia, and emaciation. The disease usually runs a rapid course, for of the cases in my list the average duration of life—dating from the first noticeable symptoms—was only 16.5 months, the longest period 26.25 months, and the shortest 8 months. Chronic forms, lasting several years, are decidedly rare.

Vaginal cancer is a disease of adult and post-meridian life; but in many cases it occurs at an earlier age than cancer in general. This causes the mean age at onset to be earlier than is usual; thus, of seventeen cases in my list, the average age at onset was only forty years, whereas the corresponding ages for the onset of uterine and mammary cancer, I have found to be forty-four and forty-eight years, respectively. The earliest age at onset was seventeen years; reputed examples of vaginal cancer at earlier ages must be viewed with suspicion; this especially applies to the oft-cited cases by Guersant, in a child three and a half years old, and by Johannovsky, in a girl of nine, in which the disease was evidently sarcomatous.

By adding my seventeen cases to Bernard's fifty-nine, a total of seventy-six cases is arrived at, the age distribution of which is as follows:

Age at onset.	Cases
20 to 30 years	in 12.
30 to 40 years	in 14
40 to 50 years	in 12
50 to 60 years	in 22
60 to 70 years	in 14
70 to 80 years	in 2

Thus, as this table shows, most cases arise long after the menopause; the decennium fifty to sixty being the period of maximum frequency. Hence it may be inferred that the origin of the disease has no direct connection with the incidents of the reproductive life. This is borne out by the fact that nulliparæ are as prone to the disease as multiparæ; for, as Bernard's data show, one-fourth of those affected have never been pregnant.

The mean fertility of vaginal-cancer patients has been estimated by West at 4.7 children per marriage, which is somewhat in excess of the normal; but when allowance has been made for the fact that a certain proportion of those affected die before the completion of the reproductive life, it is evident that their fecundity really is considerably in excess of the normal. In this they resemble female cancer patients in general; for, as I have elsewhere shown, a high degree of fecundity is a biological characteristic of all such. It thus appears that multiple pregnancies, etc., have no special influence in the causation of vaginal cancer. Neither is there any evidence in the life history of these women of any undue proclivity to miscarriages, difficult labors, previous uterine diseases, or catamenial irregularities; and they have usually enjoyed very good health prior to the onset of the cancerous disease.

Küstner obtained a history of hereditary cancerous antecedents once in twenty-two cases; but most of the clinical reports—which are generally scrappy—are silent on this subject. I made special inquiries in four cases with negative results. In a case reported by Pozzi, both of the patient's parents died of cancer—the uterus being the part affected in the mother, and the stomach in the father; the father and grandfather of Baldwin's patient both died cancerous; and in Fenger's case the grandfather died of cancer of the tongue, and an aunt of cancer of the breast.

The initial symptoms of vaginal cancer are discharge, pain, and hemorrhage; but, relatively often, the disease has made considerable progress before any indications of its existence are apparent. Of sixteen cases in my list, discharge was the first indication in nine, pain in three, a lump near the vaginal orifice in two, retention of urine in one, and inguinal adenopathy in one case. Frequency of micturition and uneasy sensations in that act and in defecation are occasionally noticed at this stage. The discharge was of a watery or leucorrhœal nature in most of the cases, generally being profuse and fetid. In several cases it was also blood-stained, especially *post coitum;* and in some markedly ichorous—excoriating the vulva, etc. Pain, as an initial symptom, is of much less frequent occurrence than discharge; in my cases the pain was generally referred to the genital, sacral, hypogastric, and inguinal regions; in one case, pain was concomitant with profuse discharge, and in another

with flooding." Pain in coitus was experienced in several cases. Although irregular hemorrhages, culminating in sanious discharge, are usual in the course of vaginal cancer I have found that hemorrhage rarely occurs as an initial symptom. Severe hemorrhages amounting to "flooding" are uncommon in this affection, and so is menorrhagia. After coitus and physical examination some hemorrhage is of frequent occurrence. The symptoms resulting from the spread of the disease and its complications, I have previously referred to.

In a minority of the cases, portions of the tumor may be visible externally or separating the labia, and it is not unusual to find the external genitalia red and eroded from contact with ichorous discharge. What is revealed by physical examination will depend upon the nature and degree of evolution of the local disease, the chief types of which I have previously described. Most vaginal cancers are of the "fragile" type, often being associated with friable excrescences or flocculent vegetation, which bleed freely when touched; and fragments are easily detachable. Firm elastic and indurated forms are, however, met with; and induration is often noticeable about the base of ulcers, the margins of which are fringed with soft vegetations. The vagina may be so occluded by extensive outgrowths of the disease, combined with the contraction consequent on infiltration, as to prevent thorough exploration of the part. Digital examination, especially by the combined vagino-rectal method, is the best means of exploration. Examination per speculum is apt to be painful, and is not always either feasible or requisite; although in suitable cases it yields valuable information. Rectal palpation should never be neglected; for, owing to most vaginal cancers being situated posteriorly, the extent of the local disease can generally be best determined by exploration in this direction, as also can the condition of the pelvic glands, most likely to be implicated, which are situated at the sides of the rectum in the vicinity of the upper part of the sacrosciatic foramen. Of course, in every case, the lymph glands in the inguinal region, and those along the course of the external iliac blood vessels, should be carefully palpated; for, in many cases, inguinal adenopathy is the chief "revealing symptom" of the disease. It should, however, be borne in mind that these glands may be enlarged and tender, merely from septic infection. Œdema of one or both lower extremities, owing to venous obstruction, is exceptionally met with.

In making the diagnosis of vaginal cancer, it must be remembered that secondary cancers of this part are of very much more frequent occurrence than primary ones; consequently, in any case of supposed primary vaginal cancer, neighboring organs likely to originate the disease must be specially examined. The uterus, rectum, vulva, bladder, etc., are among the more important of these; cancer of the cervix uteri, which is so common, nearly always spreads to the vagina sooner or later.

For the discrimination of sarcomatous vaginal tumors—clinically resembling cancer—resort must be had to the microscope.

Septically infected and sloughing myomatous tumors may generally be discriminated from cancer by careful digital examination.

I have seen a case of vaginitis verrucosa, associated with keratosis of the vaginal epidermis, in the shape of hard scabrous projections, mistaken for cancer; and some cases of chronic colpitis papulosa and kraurosis may also be similarly confounded.

Certain syphilitic, tuberculous, and "chronic inflammatory" affections may also simulate cancer, especially when they are of the ulcerative type. Syphilitic vaginal affections may be of the primary, secondary, or tertiary variety.

With regard to the first-named, hard chancres are so exceedingly rare in the vagina, and their special characteristics are so well known, that there is hardly ever likely to be any difficulty in making the differential diagnosis. Very exceptionally serpiginous chancroids have been mistaken for cancer, but the multiplicity of errosive lesions, their tendency to heal in one part while spreading in others, and other special features of this malady will enable the diagnosis to be made.

Of secondary syphilides the erosive and condylomatous forms are the ones most likely to simulate cancer; and of tertiary affections, gummata—especially when ulcerated—and diffuse infiltrations. Lang has met with a vaginal gumma, that presented a chronic tumor the size of an apple, which, after having resisted many remedies, was at last completely cured by extirpation.

In discriminating affections of this kind, which are rare, from cancer, regard must be had to the *ensemble* of the case, and especially as to the coexistence of manifestations of the disease in other parts of the body, where the signature of syphilis is likely to be found.

Tuberculous disease of the vagina is rare, but it occurs, both as miliary tubercles and as chronic ulcerations, which are usually secondary to tubercles of the lungs, peritoneum, uterus, etc. Lupus of the vagina is also met with. Lesions of this kind may even cause perforation of the bladder and rectum, as well as enlargement of the inguinal and pelvic lymph glands. Tubercular ulcers are generally multiple, and of the well-known caseating character, and indications of tubercles elsewhere, especially in the lungs, can generally be detected. With the aid of the microscope, the special bacilli may be detected in the discharge or in scrapings, and in the latter, other anatomical elements of tubercles may be found.

Under such names as "corroding ulcer," "ulcus serpiginosum," "destructive ulceration," "rodent ulcer," "ulcus rotundum simplex," "esthiomène," "lupus," "lupoid ulceration," etc., various ill-defined forms of intractable and exceedingly chronic vaginal ulceration have been described, the precise nature of which yet remains to be determined.

It seems probable that under these headings various forms of tuberculous, lupoid, and syphilitic disease are included, as well as rodent ulcer. As to whether any form of chronic ulcerative disease, answering to the description of "corroding ulcer," ever occurs in the vagina, as a consequence of local malnutrition due to obliterative endarteritis, as Zabo, Beuttner, and others maintain, I am certainly skeptical.

The surgical treatment of vaginal cancer must be regarded as an open question. In a general way, I admit the desirability of thoroughly extirpating the whole diseased area; but in most cases—such is the rapid and insidious progress of the disease—this is impracticable with any prospect of advantage to the patient. Let us hope that the earlier recognition of the malady and improved methods of operating will eventually enable us to attain better results.

The cases most suitable for extirpation are those in which the disease is limited to the vagina—especially to its posterior part—but even in cases of this kind, rapid recurrence has generally followed such operative procedures as have hitherto been employed. Simple excision of the tumor, even when freely carried out, has seldom been successful against recurrence. Martin sums up his experience as follows: "All my patients have succumbed to recurrence, although I am convinced that in nearly all of them my incisions were quite clear of the disease." The results of the more radical procedure of vaginal extirpation, as

practised by Olshauser, have been almost equally disappointing, for of sixteen patients operated on in his clinic, in fifteen the disease soon recurred, while only one was free from recurrence two years afterward.

Olshausen's procedure comprises transverse division of the perineum, so as to admit of the separation of the vagina from the rectum as high up as Douglas' pouch. The diseased part of the vagina is then separated from its connections so that it can be freely excised, together with a wide margin of the adjacent vaginal wall.

In the event of the uterus also being involved, Olshausen has practised the extirpation of both organs by the following modification of his procedure. The vagina having been separated from the rectum as high up as Douglas' pouch, the latter is opened; the uterus is then seized and retroverted; the broad ligaments and their contained blood vessels are ligatured and divided; the bladder is separated from its utero-vaginal connections; the uterus, together with the diseased part of the vagina, is then removed *en masse*, by dividing the vagina with scissors.

Among the weak points of this operation, the weakest, undoubtedly, is its failure to deal with that part of the rectum adjacent to the vaginal disease, which in such cases is nearly always implicated, except in the earliest stage of the malady.

The experience gained by such operations shows that the disease is seldom limited to the utero-vaginal canal, so that, if its extirpation is to be seriously attempted, more radical procedures are evidently necessary.

With this object in view, intervention by the sacral way and by laparotomy have been advocated. Kraske, having shown the feasibility of removing cancer of the rectum by sacro-coccygeal exsection, his operation was soon afterward modified by Herzfeld, for the extirpation of uterine cancers spreading to the vagina, rectum, etc., and this led to its utilization for the extirpation of vaginal cancers encroaching on the uterus, rectum, etc. The great disadvantage of the sacral operation, besides the restricted field, is that it offers no facilities for the removal of suspected lymph glands, etc., in the pelvis, although its mortality is considerable. In fact, the only procedure meeting all the requirements is total utero-vaginal extirpation by the abdominal route, after the manner devised by Werder for the extirpation of uterine cancer, with such small modification as to vaginal circumcision, etc., as may be necessary. In this way the whole vagina, the uterus, and its adnexa, pelvic and inguinal glands, and as much of the rectum as seems likely to be implicated, may be removed. When the bladder and periurethral tissues are infiltrated by the disease, radical operations are hardly worth undertaking.

Palliative operations comprise the removal of projecting portions of the growth with the curette, followed by the application of the actual cautery. Thus extensive sloughing, fœtid discharge, and debilitating hemorrhage may be checked. The daily irrigation of the vagina with unirritating aseptic solutions and the subsequent insertion of a light plug of iodoform gauze add to the patient's comfort. The other indications for treatment are the same as for uterine cancer.

A priori one would expect that such a disease as cancer of the vagina would prevent sexual intercourse, and be a bar to conception; but this is so far from being the case that of sixteen women of child-bearing ages with this disease in Bernard's list, no less than five were also pregnant.

This complication makes hardly any difference in the progress of the local disease; although, of course, it adds to the danger of the mother and child in parturition. Most cases go to full term, when accouchement is, as a rule, naturally effected; or the aid of forceps, or some other obstetrical manœuver, may be required to facilitate delivery.

Abortions are relatively frequent when this complication exists; but those spontaneously arising are generally less harmful than those artificially induced, owing to the frequency of septic infection under the latter circumstances. As a rule, the only surgical intervention likely to be required will be for the release of a viable fœtus. In such cases the child's interest must be the dominant consideration; and this generally requires that intervention should be deferred until as near full term as possible. When labor has actually commenced, dystocia caused by the disease may necessitate surgical intervention, of which Küstner and others have reported instances; but this is comparatively rare.

Cæsarian section is the operation usually indicated, and its results are very favorable, so far as the child's safety is concerned; but the maternal mortality is considerable.

VARIOUS METHODS OF INFANT FEEDING—BREAST FEEDING, BOTTLE FEEDING.*

By LOUIS FISCHER, M.D.,
NEW YORK.

Breast Feeding.—Nothing has yet been devised or manufactured, in spite of scientific progress, that can equal human milk. To prove this, it is only necessary to study the infant mortality of any large city, and lay special stress on the mode of feeding pursued. Then, it will be found that the large majority of infants who die, succumb for the want of breast milk. It must not be supposed that, when we have breast milk, our responsibility ends, for only the strictest supervision of the infant during the nursing period, besides regular examinations of the breast milk by a competent chemist, can determine the nature of the ingredients of the milk the baby receives.

Babies should be weighed regularly every week. The moment an infant ceases to gain in weight, the cause should be carefully looked into. The most important ingredient to study in human milk is the proteids; they are the tissue-building elements, and it will usually be noted that a deficiency of the proteid elements is associated with loss of weight on the part of the baby, and general backwardness in development.

Let me illustrate: Baby G., eight weeks old, was brought to my office. The mother stated that the infant cried constantly, had greenish, cheesy stools, and was very restless and puny. She believed it had emaciated, although she never weighed it. The examination showed a very delicate baby, with a large abdomen, quite tympanitic on percussion; the skin appeared dry, and the muscles flabby. Some rhonchi on both sides of the thorax showed a bronchitis; the heart was feeble, but quite regular in rhythm. The buttocks were very red from excoria-

*Read in part before the Harlem Medical Association of the City of New York.

tions, evidently due to excessive irritation from acid stools. On questioning the mother, I learned that the baby nursed from one-half hour to forty-five minutes, and then cried almost continually until the next feeding time. When the child slept, the mother did not notice any discomfort from her overfilled breasts, and she never had the distinct "rush of milk" so natural to the beginning of the nursing act. A drop of breast milk was taken several minutes after the nursing act was properly established, and examined under the microscope, in order to study the character of the emulsion. By this means the size and form of the fat globules could be determined, and a rough estimate of the value of the milk could be made. This is not, however, a positive criterion of the exact value of the milk, and to determine this, the contents of a full breast of milk should be drawn off and sent to the chemist. By excessive stimulation, and prolonging the time for nursing, I was only able to draw off about an ounce of breast milk, showing a deficiency in quantity. The examination made for me by Mr. Graeff, a chemist, showed the following result:

Fat	3.35
Sugar	7.35
Proteids	1.08
Water	88.12
Inorganic salts	0.20
Casein (probably)	0.40
Albumin (probably)	0.68
Total solids	11.88
Specific gravity	1.0309

Reaction, alkaline (slightly).

The casein and albumin could not be separated, owing to the small sample of milk submitted to the chemist.

On studying the ingredients of this breast milk, we note that the fat and sugar were normal in quantity, but that the proteids were very low.

The supply being scanty, mixed feeding was tried in the following manner: The infant was fed every two and a half hours from the breast, alternating with a bottle feeding. The milk prescribed in the bottle was ordered at a laboratory, and contained:

Fat	2.00
Sugar	5.0
Proteids	0.7

Raw milk. No alkalinity. Number of feedings, five; quantity, three ounces.

The infant improved, as noted, by increase in weight. Yellowish stools were passed not more than three in the twenty-four hours. The child seemed satisfied after feeding, as the mother stated; it frequently slept from one feeding time until the next.

Ten days after the method of mixed feeding was commenced, the infant's mother reported that her milk was so scanty that she had hardly enough to nurse the baby twice in twenty-four hours, so that it was necessary to substitute bottle-feeding entirely, with the exception of one morning breast feeding and one evening breast feeding. I am rather opposed to giving up breast milk, no matter how little may be present, and always aim to supply the deficiency by judicious hand feeding. But in this instance the total cessation of breast milk compelled me to substitute bottle feeding.

It would almost seem out of place to offer a plea for the hapless baby to obtain breast milk were it not for the fact that thousands of children are lost because of "scientific methods" of feeding—methods aiming at exactness, but in reality being far from exact, when the results obtained are carefully studied. Nothing will ever be able to supersede the simple human breast milk, wherein nature gives a clean alkaline emulsion of the proper consistency as to both quality and quantity, and without the necessity of first passing through complicated manipulations before feeding.

The duty of the physician is to note the condition of the human breast after the birth of the baby, and to examine carefully the specimen of milk the moment any signs of trouble manifest themselves in the infant. Such symptoms are: Colic, gastric disturbances, frequent vomiting, and the passage of excessive greenish or cheesy stools. When such symptoms are present, a chemical examination of the milk is demanded to judge of the quality of the food. An important point, and one that I lay great stress upon, is to take the weight of the infant. It is necessary to weigh the baby at least once a week. A stationary weight or loss of weight will at once direct our attention to the fact that the infant receives milk that is poor in either quality or quantity, or possibly in both. So closely is the infantile mortality associated with the manner of feeding that we can tell at a glance just what manner of feeding has been pursued.

According to reliable statistics, in Norway the mortality from breast feeding only ranges between 8.5 and 10.5 per cent.; in Bavaria, where children are largely brought up on farinaceous foods, the mortality is about 30 per cent. Out of four hundred children dying from summer diarrhœa, Minert, in Bavaria, observed that 96 per cent. were artificially fed.

During times of great distress, as, for example, during the siege of Paris and the Lancashire cotton famine, the infant mortality is largely reduced, while adult mortality is increased—this being due to the fact that mothers at such times are compelled to suckle their babes.

Ballord made a prolonged and careful investigation into the causation of infantile diarrhœa, with the following results: (1) Infants in all conditions of life, fed solely from the breast, are remarkably exempt from fatal diarrhœa; (2) Infants, fed in any way with artificial food, "to the exclusion of breast milk," suffer the most heavily; (3) Infants, fed partially on the breast and partially on artificial food, occupy an intermediate position; (4) The "bottle" is the most dangerous method of artificial feeding. In other words, the excessive mortality among infants from diarrhœa is due to the method of feeding, that is, to artificial food, and the mode of its preparation and administration. The food may be, in itself, sound and wholesome, and yet dangerous, because unsuited to the digestive capacity of the child; or, it may be perfectly suited to the child's digestion and requirements, and yet dangerous from having been stored in dark, ill-ventilated places, exposed to infection from soil, drains, etc.; or, it may happen that the food is wholesome and suited to the digestive capacity of the particular infant, while the evil result is due to dirty feeding bottles, rubber tubes, or nipples, or to overfeeding and irregularity in feeding. In artificial feeding, there is less liability to diarrhœa and other forms of digestive disturbance when the food is given from a clean cup or a clean teaspoon than when a bottle of any description is used.

Speaking of the mortality in infants in the maternal management of children, Thomas Bull says: About a century ago, the workhouse in London presented the astonishing result of twenty-three deaths in every twenty-four infants under the age of one year.

Parliamentary inquiry resulted in improved management, and thus the deaths were quickly reduced from 1,600 to 400 a year.

Again and again have I seen a sickly and delicate child become vigorous and healthy under a judicious system of hygiene and feeding.

In other instances, an infant born strong and

healthy, has withered, pined, and died, simply from bad feeding and bad management.

Cautley, in his book on infant feeding, gives reasons for a large infant mortality thus:

The more rural the district, the lower is the infant mortality.

The more industrial the town, the greater is the infant mortality.

Causes are either:

(1) Insufficiency of fresh air in towns, and bad hygienic surroundings; (2) Deficient or contaminated milk supply for bottle-fed infants; (3) The lack of breast milk. So many mothers wean their children.

The number of deaths from diarrhœal affections at this early age is a fair indication of the mortality from unsuitable feeding.

We note, however, that in England in 1894, minor causes of death under one year of age were: Thrush, 334; starvation or want of breast milk, 231; scurvy, 8; rickets, 445; dentition, 2,155; enteritis, 3,247; tabes mesenterica, 2,945; convulsions, 15,775; and many other causes directly or indirectly connected with the mode of feeding.

NEW YORK CITY STATISTICS.*

Population, Deaths, Death Rate of Children, under five years of age, from 1891–1900.

Year.	Population.	Deaths.	Death Rate.
1891	188,703	18,224	96.6
1892	194,214	18,684	96.2
1893	199,886	17,865	89.4
1894	205,723	17,558	85.3

	153	100	18	14	68	76

Eröss collected statistics from sixteen cities of Europe, and found that of 1,439,056 children born, there died 130,610 during the first four weeks of their life, or nearly 10 per cent.

Two hundred deaths; their mode of feeding. Inquiry into 200 deaths taken by me at random at the Children's Service of the German Poliklinik and West Side German Dispensary.

Age in Months.	On Breast only.	Breast Partially.	Bottle Feeding only.
0–3	5	8	16
3–6	7	12	24
6–9	12	16	39
9–12	9	12	40
Totals.	33	48	119

The above children were all inhabitants of both the east and west side of the city, living in crowded apartments known as tenement houses. The hygienic factor is, therefore, an important one. Sixty per cent. of these children died from gastric and intestinal disease; about 30 per cent. died from catarrhal diseases, affecting the air passages, such as bronchitis, pneumonia, and tuberculosis. The rest died from infectious diseases and surgical accidents.

It is idle to believe that, because an infant is nursed by its mother, all must go well. That this is not always true can be seen by the careful examination of the baby, which I have the honor to demonstrate, and whose rickets and spinal disease are as severe as the worst specimens encountered from faulty bottle feeding.

M. G., one year old, has been breast-fed since birth. His mother notices that he cannot stand nor walk nor talk. His dentition is delayed, and he has no tooth yet. Two other children were far more advanced at the age of nine months than this child is at twelve months. The mother states that she has lost no children, and has never miscarried. Lues can be positively excluded.

The infant's bowels have always been troublesome, either constipation or diarrhœa being present. The child at present is troubled with greenish, offensive, cheesy, curded stools. He is still nursing, as often as every two hours, and when crying or restless, the mother nurses the baby oftener. He takes the breast several times at night.

A drop of breast milk, placed under the microscope with a low power, showed a very poor emulsion with irregular-shaped fat globules. It also presented the following conditions:

Reaction: Very slightly alkaline.

Specific gravity	1.031
Fat	0.96
Sugar	7.67
Proteids	0.88

March 23, 1901

What impresses one most in the study of this case is the fact that the bony structures are imperfect and lacking in their solid elements.

The child has a square head—the typical rachitic head—beaded ribs, the usual rachitic rosary, pendulous belly, and flabby condition of the muscular walls of the gastro-intestinal tract. The ends of the long bones, particularly the radius and ulna, tibia and fibula, show rachitis. The spine presents a marked rachitic kyphosis.

Thus, the whole osseous system seems to suffer from lack of proper food, and we have especially in the bones evidence of malnutrition.

Could this condition have been avoided, and how?

My answer is, by carefully watching the ingredients of the breast milk, the rachitic manifestation could have been stayed. We know that toward the end of lactation, or about the end of six months, the albuminoids of the milk decrease, and, unless we make up this deficiency by giving the infant some food containing proteids, such as beef broth or meat soups or raw white of egg, in addition to the breast feeding, the period of dentition will be delayed. In addition to the physiological deficiency, the bony structures

suffer and will be soft, thus inviting spinal curvatures or bow-legs or some similar bony deformity.

Under such circumstances, the breast milk should be examined by a chemist, and, if the ingredients are noted, we can study just what portion of the milk is lacking.

If the milk deteriorates rapidly, and the infant's weight shows no gain, or a possible loss of weight, then weaning must be insisted upon.

Frequently, careful attention to the mother's diet and the administration of nitrogenous food, in addition to outdoor exercise, will work admirably.

2. Mixed Feeding.—The following case will illustrate what is meant by "mixed feeding":

Baby E., about three weeks old, was referred to me by Dr. H. Jareeky. The child had greenish, sour-smelling, cheesy stools. The mother states that the infant is very restless, shrieks as though in pain, and vomits very frequently. The emesis is of an explosive character.

A drop of milk placed under the microscope showed the globules of fat very unequal in size, and very unevenly divided. It is a very thin emulsion. A specimen sent to a chemist showed the following:

Specific gravity	1.035
Reaction	Neutral.
Fat	2.46
Sugar	7.47
Proteids	1.24
Total solids	11.37
Inorganic salts	0.22
Water	88.61

On studying the above, we note that there is a great deal of sugar, enough fat, and also proteids, and that the milk, while quite good in quality, was only deficient in quantity. Attention was, therefore, directed to the mother's general health, and out-of-door exercise, a careful attention to her bowels, and a nitrogenous diet, consisting of meat, milk, and eggs, was ordered. She was instructed to nurse the child every four or five hours only, and to substitute a bottle containing three ounces of a milk mixture, consisting of

Raw milk	1 oz.
Oatmeal water	2 ozs.
One-half teaspoonful granulated sugar.	
A pinch of salt.	

This mixture was warmed before feeding, and was neither sterilized nor pasteurized.

This was fed alternately with the breast milk. Thus, the child received a breast feeding at 8 A.M., bottle feeding at 10.30 A.M., breast feeding at 1 P.M. It is a good plan to take a child up during the day from its sleep, if it is feeding time, and in this manner try to pursue regular intervals of feeding by day, to discourage regular feeding at night, and try to encourage sleep.

The general condition of this baby was very good, as a careful study of the weight chart will show, and so I gradually changed from oatmeal to barley water. The child is now a little over three months old, and receives the following formula:

Milk	2 ozs.
Barley water	2 ozs.
Pinch of salt.	
Half teaspoonful granulated sugar.	

Scald the raw milk with the hot barley at the time of feeding. No other pasteurization or sterilization is required. Feed every six hours with a bottle, alternating with the breast. Thus, the child receives its mother's breast or its bottle once every three hours. The stools are yellow and of a good consistency. The vomiting, which was very disagreeable, has greatly improved.

It was quite apparent that what first appeared from the clinical history to be explosive vomiting due to some cerebral disease (possibly meningitis) proved to be due to fermentative gastric trouble.

Baby born, December 19, 1900.

	Weight
December 19 (at birth)	8 pounds
December 26	7½ "
January 3	7 "
January 11	7 "

Commenced treatment:

January 18	7½ lbs.	Gained 8 ounces.
January 25	7 lbs. 10 oz.	" 2 "
February 1	8½ lbs.	" 12 "
February 8	9½ lbs.	" 16 "
February 15	10 lbs.	" 8 "
February 22	10½ lbs.	" 8 "
March 1	10 lbs. 14 oz	" 6 "
March 10	11 lbs. 7 oz.	" 9 "
March 24	11 lbs. 14 oz	" 7 "

3. Bottle Feeding.—When breast milk cannot be obtained then pure cow's milk should be used for bottle feeding. The ideal milk "is milk which has been secured from a reliable dairy in which all modern sanitary laws are so applied that the hygienic condition of the cow's stable is perfect."

If milk is bought from the average dairy in New York City, it is rarely less than from twenty-four to forty-eight hours old. Such milk certainly requires pasteurization or sterilization if we are compelled to use it for the feeding of infants. It must not be supposed that sterilizing or pasteurizing milk which is contaminated with either pathogenic or non-pathogenic bacteria will alter its quality, for we cannot convert an unhealthful milk into a healthful milk by any steaming process yet devised. Toxins contained in milk, and which are always elaborated by micro-organisms, cannot be destroyed even by subjecting the milk to a temperature of 300° F.

Public benefactors commence at the wrong end when they seek to convert milk contaminated with bacteria into a sterile fluid by steaming the same. What is gained by means of the boiling or steaming of the milk is simply the destruction of a large number of bacteria. It is impossible to destroy all micro-organisms unless the milk is subjected to tyndallization, which really means renewing the sterilization on three successive days for a given time. That this is impractical and next to impossible is at once apparent.

Objections to sterilized or steamed milk consist in the fact that the heated milk has undergone chemical changes. The latter are chiefly found in the casein, which is rendered much more indigestible when heated. All heated milk has a tendency to constipate, and it is only necessary to compare the stools of two children; one child being fed on raw milk, the other on heated milk. It will be found that the digestibility of the raw-milk baby will be far greater than that of the steamed-milk baby. In other words, the stool of a baby fed on raw milk will be of a more homogeneous consistency than that of the other baby fed on sterilized or pasteurized milk.

The greatest objection to feeding with sterilized milk consists in the fact that the majority of such children offer a greater tendency to the development of scurvy and rickets. Milk that is steamed or boiled lacks the element of freshness, which, we know, will produce scurvy, the same as happens when an adult is deprived of fresh meat and green vegetables.

Only recently K. Oppenheimer, in Munich, published a series of experiments in the *Deutsche medicinische Wochenschrift*, February 14, 1901, showing that milk generates H S when heated longer than five minutes. He used filtering paper saturated with acetate of lead, and noted the increasing brownish-black deposit, depending on the length of time that the milk was heated. Thus, while milk heated five

minutes showed a brownish color, that heated twenty minutes converted the filtering paper saturated with lead solution into an intense blackish-brown color. Oppenheimer, therefore, believes, based on his experiments, that the albuminoids, or, more properly speaking, the albumin in milk, is decomposed, as proven by the liberation of sulphureted hydrogen, after milk is heated five minutes or longer in a steamer.

The following case taken from my clinical notes will serve as an example of how to feed with raw milk: An infant, seven months old, had been wet-nursed, and was brought to my office with the following history: The child has been well until it was six months old, seemed to gain in weight from six to eight ounces weekly, and appeared satisfied after nursing. The stools had been quite regular up to one month ago; since one month the infant's weight remained stationary, the stools had been of greenish color, contained many curds; the infant was very restless and wanted to nurse all the time; the child did not appear satisfied, and seemed to cry most of the time. The breast milk was sent to a chemist, who reported the following:

Amount sent, 1½ ounces.	
Reaction	slightly alkaline.
Specific gravity	1 03105
Fat	1 22
Proteids	0 98
Sugar	7 07

It was also learned from the clinical history that the wet-nurse had menstruated quite profusely for one week, and during that time the baby seemed to be colicky. After receiving the above chemical report, which showed the deficiency of both fat and proteids, I ordered the child weaned. The following food was then prescribed:

Raw milk ..... 6 ounces.
Barley water ..... 2 "
Half teaspoonful granulated sugar.
Pinch of salt.

Warm the milk in a water bath for three minutes before feeding. Feed every four hours.

On the alternate days I ordered:

Raw milk ..... 6 ounces
Oatmeal water ..... 2 "
Half teaspoonful granulated sugar.
Pinch of salt.

Warm the milk before feeding, and feed the baby every four hours.

Thus, the baby received one day oatmeal with milk, and the following day barley with milk. In order to give the child something that would act as a general tonic, I ordered tablets containing one minim of nux vomica, to be given three times a day before the feeding, dissolved in a teaspoonful of water.

The stools were carefully watched, and the mother reported that twenty-four hours after commencing this raw-milk feeding, the stools were yellowish, and the child seemed to be satisfied. One week following this plan of treatment, the child gained six ounces; at the end of two weeks fourteen ounces more, making a total gain of twenty ounces in two weeks. It must be understood that each child must be watched carefully, and that we must aim at the gradual substitution of whole milk, rather than give milk diluted with the cereals as above prescribed. If, therefore, the appetite warrants it, seven ounces of milk can be given to a baby, as above described, diluted with one ounce of rice or barley water; this to be followed in a few weeks—if the stools, the general gastric condition, and the absence of vomiting will warrant it—by pure cow's milk.

In the case reported, I ordered the white of a raw egg, with some sugar, fed with a spoon, and also gave the child some steak juice, or roast-beef juice, or a concentrated soup made from meat containing sago, farina, or hominy, at noon, midway between the milk feeding.

The average child requires about one quart of cow's milk divided into four portions of eight ounces each. In addition a bread pap, consisting of crackers or zwieback, soaked in soup, will be found advantageous. It is worthy of note that, three weeks after I commenced the above change from the wet-nurse to the cow's milk, an eruption of two lower teeth made their appearance.

108 East Ninetieth Street

ON THE PRESENCE OF TYPHOID BACILLI IN THE BLOOD OF TYPHOID-FEVER PATIENTS.

By ALBION WALTER HEWLETT, M.D.,
NEW YORK HOSPITAL

Since 1885, isolated cases have been reported in which typhoid bacilli have been cultivated from the blood during the course of typhoid fever. Within the last two years, it has been shown by the use of delicate methods that the bacilli occur in the blood of the majority of typhoid-fever patients. The following are the recent figures:

Castellani,[1]	1st series, 12 cases	9 positive, 0 per cent.
	2d series, 14 cases	12 positive, 87 per cent.
Schottmüller[2]	50 cases	40 positive, 80 per cent.
Auerbach and Unger[3]	16 cases	7 positive, 70 per cent.
Cole[4]	15 cases	11 positive, 73 per cent.
Present series	24 cases	20 positive, 83 per cent.

1. Castellani, Aldo: "Sul Reporto del Bacillo Tifico nel Sangue"—*La Rif. Med.*, 1900, Vol. I, pp. 63 and 70.

2. Schottmüller: "Ueber eine das Bild des Typhus bietende Erkrankung hervorgerufen durch Typhus ähnliche Bacillen"—*Deutsche medicinische Wochenschrift*, Vol. 26, 1900, p. 511.

3. Auerbach, Max, and Unger, Ernst: "Ueber den Nachweis von Typhusbacillen im Blut Typhus Kranker"—*Deutsche medicinische Wochenschrift*, Vol. 26, 1900, p. 746.

4. Cole, Rufus I.: "Frequency of Typhoid Bacilli in the Blood"—*Johns Hopkins Hospital Bulletin*, Vol. XII, 1901, p. 205.

The great certainty of such a means of diagnosis led to a systematic test of its value in a series of cases at the New York Hospital. Cultures were made from the blood of twenty-four typhoid patients. Of these, seventeen showed typhoid bacilli in the first cultures, and three more showed them during the relapse, a total of twenty positive cases out of twenty-four, or 83 per cent. of the number investigated. Of sixteen consecutive cases from the male and children's wards, typhoid bacilli were obtained from the blood of fifteen, showing that the above percentage was not raised by a selection of patients.

The method employed in making blood cultures was essentially the same as that used by Cole. About five cubic centimeters of blood were taken from a vein at the elbow and were diluted in three flasks of sterile bouillon. If a growth of motile bacilli appeared, they were identified by their reaction toward a known serum, a well-marked Widal reaction after ten minutes in a dilution of one to ten being considered as sufficient to establish a diagnosis. Staphylococci appeared in a small number of the cultures and were regarded as contaminations. When the bacilli in the original flasks of bouillon grew out rapidly and were sufficiently motile, a positive result could be obtained in thirty hours. If a transfer or plating was necessary, the identification of the bacilli was often delayed for from three to five days. These delays constitute the most serious objection to the use of blood cultures for early diagnosis and indeed often rendered its use most disappointing. Two factors are important in the above method: the

use of large quantities of blood and the dilution of this blood in sufficient bouillon so that its bactericidal properties will not prevent the growth of organisms. Castellani lays especial stress on this second factor and attributes his success in his second series of cases to the large amount of diluent used. The importance of the first factor will be shown later.

Castellani mentions four cases in which typhoid bacilli were obtained in blood cultures at a time when the Widal reaction was negative. Auerbach and Unger report one such case. Cole obtained the bacilli in six cases before securing a positive Widal reaction with a dilution of one to fifty. In three of our patients (III, V, XV), the blood contained typhoid bacilli before the serum, diluted one to ten, showed the Widal reaction.

The present series of cases shows that cultures taken early in the disease are more apt to be positive than those taken late in the disease. In all, thirty-eight blood cultures were made from twenty-four patients, with the results here tabulated:

Days of Disease.	3	4	5	6	7	8	9	10	11	12	13	14	16	17	19	20	21	22	23	27	33

						+			—				—								
						+							—								

The earliest positive results in the course of the original fever were obtained on the fourth and fifth days of the disease. The difficulty in determining the exact onset of the illness, however, makes these days somewhat uncertain. Of three cases in which cultures were made during a relapse, all showed typhoid bacilli in the blood. In these, the onset of the relapse could be accurately determined, and the positive results were obtained in them on the third, the fourth, and the fifth days. Previous cultures in each case had been negative, so that a fresh blood infection had probably occurred at these early dates in the relapse. The earliest negative results, obtained twice on the eleventh day, were in rather mild cases (IX and XXI). From only two patients were cultures positive after the fourteenth day of the disease, and in none was a positive result obtained after a previously negative culture, except when there was a relapse. Of the two patients showing positive cultures in the third week of the disease, one (XVII) was a severe and fatal case of ambulatory typhoid, positive on the twentieth day. The other case (XXII) ran a moderately severe course and was complicated by phlebitis of both femoral veins. Blood cultures taken on the seventeenth day showed typhoid bacilli; those taken on the twenty-first day were negative. Typhoid bacilli have been obtained from patients at the beginning of the fourth week of the fever, in one instance by Cole, and once by Auerbach and Unger. There was no such case in the present series. On the other hand, cultures were negative during the third week of the disease in several of our severe cases (XII, XVII, XXII). One of these patients (XII) appeared to be most intensely intoxicated. Nevertheless, blood cultures on the sixteenth and twentieth days were negative, and the bacilli were only obtained with the onset of an intercurrent relapse. Case XVI ran a moderately severe and very protracted course. Cultures were positive on the eighth and thirteenth days; negative on the nineteenth and thirty-third. At the time of the last, the afternoon temperature had been regularly above 102.6°. Successive blood cultures during the fever were made in a number of other cases. In case III, they were positive on the fifth and eleventh days; in case XV, on the fourth and tenth days; in case IX, they were positive on the ninth and negative on the twenty-second day; in case XXIV, positive on the fourteenth and negative on the nineteenth day.

Typhoid bacilli have been obtained from the blood of typhoid-fever patients during the relapse, by Cole and by Auerbach and Unger. In the three cases of the present series in which cultures were made during the relapse, typhoid bacilli were found very early in each case. As previous cultures during the fever had been negative, it must be inferred that a fresh invasion of the blood occurred at the onset of the relapse. One of these relapses was exceedingly mild in character. The patient had no subjective symptoms, the temperature rose only once above 102.6°, it touched normal on the seventh, and remained there after the twelfth day. Hardly a better illustration could be found to show that typhoid bacilli may occur in the blood during a very mild course of fever.

All who have made blood cultures agree that bacilli may be obtained from the blood of very mild cases, and that, on the other hand, they may be absent from much more severe ones. As has been stated, the present series tends to confirm these views. We were inclined to attribute our negative results in severe cases to the late period of the disease at which the cultures were taken. However, Cole's case, No. XII, cannot be thus explained. This was a severe type of the disease and proved fatal. Blood cultures were negative on the ninth, fifteenth, and twenty-third days. The cultures were made, however, in tubes instead of flasks of bouillon.

The number of bacilli present in the circulating blood in an ordinary case of typhoid fever is doubtless small. A fluid culture medium can give but little information in regard to the number present. Nevertheless, it was found not infrequently that only one or two of the three flasks of bouillon inoculated developed typhoid bacilli, the others remaining sterile. It was noted on several occasions also that where a growth occurred in only one flask, that flask was the one which contained the largest amount of blood. This would seem to indicate, on the one hand, that the number of bacilli present in the blood is very small indeed, and, on the other, that the most essential factor in this method of making cultures is the large amount of blood used rather than a very high dilution of the blood.

To attempt generalizations from such a limited number of cases hardly seems justified. This series, however, leads one to the view that there is in the great majority of cases of typhoid fever an invasion of the blood with bacilli during the early weeks of the disease. It is not, however, properly a septicæmia, for the number of bacilli present is ordinarily very small. During the third week of the disease, or at any rate at about the time the temperature begins to fall, bacilli are no longer to be obtained in blood cultures. With the onset of a relapse, the bacilli reappear in the blood, only again to disappear as the relapse subsides.

Case I.—F. R. (No. 5501), aged forty-four years, was admitted May 24, 1901, about the third day of the disease. The case was one of moderate severity, complicated by intestinal hemorrhages and orchitis. Rose spots were present on the sixth day. Widal reaction was suggestive on the fourth and sixth days, and blood cultures positive on the sixth day.

Case II.—A. A. (No. 5504), aged thirty-four years. Admitted May 25, the twenty-first day of the disease. A moderately severe course, complicated by a suppurative mastitis, from which typhoid bacilli were obtained.

On admission, the spleen was palpable, rose spots were present, and the Widal reaction was positive. Blood cultures on the twenty-third and twenty-seventh days of the disease were negative.

Case III.—F. B. (No. 5623), aged twenty-nine years. Admitted June 10, the fifth day of the disease. A moderately severe case. Definite rose spots on the ninth day. Widal reaction was negative on the fifth and eighth days, but positive on the thirteenth day. Blood cultures showed typhoid bacilli on the fifth and eleventh days.

Case IV.—A. W. (No. 5662), aged nineteen years. Admitted June 17, the fifteenth day of the disease. A case of moderate severity, followed by a relapse. On admission, the spleen was palpable, rose spots were present and the Widal reaction was positive. Blood cultures made on the sixteenth day were sterile. Only small amounts of blood were used.

Case V.—R. O. (No. 5978), aged twenty-one years. Admitted July 31, the sixth day of the disease. A severe, protracted case, with continued fever of forty-two days' duration, ending fatally. On admission, spleen was palpable and rose spots were present. Widal reaction was negative on the seventh, ninth, and twelfth days; positive on the fifteenth day. Blood cultures positive on the eighth day.

Case VI.—R. M. (No. 5989), aged twenty-nine years. Admitted August 3, the eighth day of the disease. Severe course, ending in death from intestinal perforation. On admission, rose spots were present, the Widal reaction was positive, and the area of splenic dulness was enlarged. Blood cultures positive on the ninth day.

Case VII.—T. S. (No. 6025), aged twenty-two years. Admitted August 8, the fourteenth day of the disease. A severe illness, terminating fatally on the twenty-eighth day, and complicated by intestinal hemorrhages, bronchopneumonia, and submaxillary adenitis. On admission, the spleen was palpable and the Widal reaction was positive. Blood cultures positive on the fourteenth day.

Case VIII.—A. F. (No. 6028), aged twenty-nine years. Admitted August 9, the seventh day of the disease. A severe and protracted course, with recovery. On admission, the spleen was palpable and the Widal reaction positive. Two days later, rose spots appeared. Blood cultures were positive on the seventh day.

Case IX.—G. F. (No. 6157), aged forty-nine years. Admitted September 3, the ninth day of the disease. A mild case, with a very mild relapse. Few suspicious spots on abdomen. Spleen not palpable. Fairly good Widal reaction. Blood cultures on the eleventh day sterile. On the thirty-fourth day, the fifth day of the relapse, blood cultures were positive.

Case X.—W. S. (No. 6159), aged eight years. Admitted September 3, about the fifth day of the disease. Mild course. On admission, the spleen was palpable, rose spots were present, and the Widal reaction was positive. Blood cultures were positive on the seventh day.

Case XI.—G. A. (No. 6197), aged thirty-four years. Admitted September 9, on the fifteenth day of the disease. Very mild course. Area of splenic dulness enlarged. No rose spots; Widal reaction was positive. Blood cultures on the sixteenth day remained sterile.

Case XII.—C. D. (No. 6212), aged twenty-nine years. Admitted September 12, the fourteenth day of the disease. Severe course, with severe relapse. On admission, a few rose spots and a positive Widal reaction. Spleen palpable on the seventeenth day. Blood cultures were negative on the sixteenth and twentieth days, but positive on the thirty-first day, the third day of the relapse.

Case XIII.—H. G. (No. 6214), aged nine years, was admitted September 12, the eighth day of disease. The symptoms were moderately severe, and were complicated with double otitis media. Widal reaction positive on admission. Spleen palpable five days later. Blood cultures positive on the eighth day.

Case XIV.—E. S. (No. 6217), aged eleven years. Admitted September 13, the fifth day of the disease. Widal reaction positive on admission. Spleen palpable four days later. Blood cultures positive on sixth day.

Case XV.—C. G. (No. 6228), aged twenty-seven years. Admitted September 16, the fourth (?) day of the disease. Severe course, ending in death on the sixteenth day. On admission, suspicious rose spots, and spleen not palpable. Widal reaction suggestive on fourth day, positive on the sixth day. Blood cultures positive on the fourth and tenth days.

Case XVI.—J. E. (No. 6230), aged thirty-one years. Admitted September 17, the seventh day of the disease. Mild course. On admission, the spleen was palpable and the Widal reaction positive. Blood cultures positive on the eighth and negative on the twenty-third day.

Case XVII.—T. B. (No. 6278), aged thirty-two years. Admitted September 26, the fifth day. A moderately severe but very protracted course. On admission, the spleen was palpable and the blood gave a fairly good Widal reaction. Blood cultures positive on the eighth and thirteenth days, negative on the nineteenth and thirty-third.

Case XVIII.—E. M. (No. 6282), aged thirty-two years. Admitted September 20, the nineteenth day. Severe case of ambulatory typhoid, ending in death from intestinal perforation. On admission, rose spots present. Widal reaction positive and area of splenic dulness enlarged. Blood cultures positive on the twentieth day.

Case XIX.—J. C. (No. 6287), aged thirty-seven years. Admitted September 27, the ninth day of a mild but rather protracted course of fever. On admission a few suspicious spots; the Widal reaction was positive, spleen not palpable. Blood cultures positive on the ninth and negative on the twenty-second day.

Case XX.—B. E. (No. 6307), aged twenty-eight years. Admitted October 1, the eleventh day of the disease. Protracted course with an intercurrent relapse. On admission, spleen was palpable, rose spots were present and the Widal reaction was positive. Blood cultures positive on the twelfth day.

Case XXI.—J. N. (No. 6355), aged thirty-four years. Admitted October 7, the eighth day of the disease. Rather mild course, with moderately severe relapse. Spleen not palpable. Few suspicious spots on admission. Widal reaction negative on eighth, fairly good on ninth and nineteenth days. Blood cultures negative on the eleventh day and positive on the twenty-sixth, the fourth day of the relapse.

Case XXII.—J. L. (No. 6393), aged twenty-six years. Admitted October 14, the sixteenth day of a moderately severe course of typhoid complicated by phlebitis of both femoral veins. On admission, there were a few rose spots and the Widal reaction was positive. Blood cultures were positive on the seventeenth and negative on the twenty-first day.

Case XXIII.—T. C. (No. 6403), aged twenty-nine years. Admitted October 17, the fifteenth day of a rather severe course of fever. Widal reaction positive on admission. Blood cultures negative on the sixteenth day.

Case XXIV.—C. K. (No. 6424), aged seventeen years. Admitted October 19, the fourteenth day of a mild course. On admission, the spleen was palpable, rose spots were present, and the Widal reaction was positive. Cultures were positive on the fourteenth and negative on the nineteenth day.

A DEVICE FOR IRRIGATING THE MALE BLADDER.

By U. S. BIRD, M.D.,
TAMPA, FLA.

Irrigation of the male bladder by the urethra may be done by two different methods: One, in which an instrument is introduced into the bladder, and another, in which this is avoided. The last is preferable. Some reference to both is necessary.

The first is sometimes difficult and always risky. The passage of an instrument into the normal male bladder is usually easy. Difficulty and disease are associated. This difficulty is of all degrees, to impassability, which latter has been in the writer's experience. Only rigid instruments are usually adapted to difficult cases. The uncertainty and risk may be due to one or all of the following causes: Manipulation, a dirty instrument, an infected urethra, or an objectionable lubricant. In some individuals, the aseptic introduction of an instrument causes undue trouble. Pain, chill, fever, and varied nervous phenomena have been observed. We can be fairly secure in the condition of our instruments, although even here we may unwittingly fail. The writer recalls an instance of a metal catheter which was frequently used, and at least as frequently boiled, and supposed to be clean. On one occasion it was held in a flame and some frying was noticed. Continuing to apply this heat, the contained grease and its contents melted and burned for two minutes or more. If we can be sure of our instruments, the same cannot be said of the urethra. In supposedly clean cases it is uncertain. In known infection the certainty is negative. The condition of an instrument passed

into a suppurating urethra admits of no question. The danger from such an instrument in the bladder is just as indubitable.

In introducing instruments into the bladder, a lubricant is necessary. Glycerin and soaps are used in order to dispense with oils. They are unsatisfactory, except, perhaps, for a single introduction. Even then a soft-rubber catherer will sometimes need an oil. In repeated irrigation of the bladder a soft catheter is preferable, and without some agent, as vaselin, unpleasant friction with consequent irritation and possible infection may be noticed. Even vaselin will not entirely obviate this, but it is the best. Some part of such lubricants is left in the urethra with a probability of harm. Soaps and glycerin are similarly objectionable, but in a less degree.

By avoiding the introduction of an instrument into the bladder, the above risks and dangers are, in a great measure, avoided, but not entirely. The passage of a liquid into the bladder cannot be absolutely safe, because it is a foreign body, although a less objectionable one than a solid instrument.

For some time, irrigation of the bladder has been practised by means of gravity. In 1898, Guiteras mentioned using a fountain syringe, high enough to overcome the resistance of the cut-off muscle.

In the writer's genito-urinary work, irrigation of the bladder has been frequently necessary. At first, a soft-rubber catheter in the bladder and gravity were used. In doing this it was noticed that occasionally liquids would enter the bladder while the catheter was yet in the urethra. Thus was done, accidentally, the operation mentioned by Guiteras. But it was never done with the ease and certainty to make it a dependence, so the use of the catheter in the bladder was continued. In some cases it was impossible to introduce a soft-rubber catheter more than once because of irritable spasm.

In using gravity and pressure on the glans, with a catheter, in irrigating the posterior urethra, it was noticed that a certain manipulation of the floor of the urethra, as rhythmic compression, caused liquids to enter the bladder. This was such an improvement on the gravity method, which frequently failed, that it became a routine procedure, as it rarely failed. But, although effective, it was tedious and hence painful. An extension of the idea led to manipulation of the rubber tube, thus avoiding unpleasant manipulation of the urethra. This was a distinct advance, as greater latitude in pressure was possible, and hence greater certainty of result. However, the operation was still slow, indirectly causing pain by continued pressure on the glans. For some time, this method was used exclusively and satisfactorily, as it was the best known. In casting about for a means of avoiding the drawbacks of slowness and consequent pain, the similarity of pressing a tube and a bulb was intuitively perceived, and the next improvement was the logical result. The bulb and discharge tube of a bulb syringe were connected to the tube of a fountain syringe, a hard nozzle guarded by a soft-rubber tip supplaced the catheter, and the apparatus which is presented was complete.

The details of its use are simple. The reservoir containing the irrigating liquid is raised to a convenient height; the nozzle is introduced into the meatus, and pressure sufficient to prevent escape of liquid is made with the thumb and forefinger on the glans and urethra around the nozzle, and the bulb is compressed. The use of gentle, slowly increased, and regulated pressure will cause the liquid to enter the bladder, and the rest is easy. The bladder is emptied naturally, and the operation repeated as indicated.

The drawbacks to this method are less than those attendant on any other known to the writer. The results of introducing a liquid into the bladder are uncertain. But an antiseptic solution is safer than a solid instrument. Some urethræ do not well tolerate pressure necessary to enter the bladder. The pain or other unpleasantness is reduced to a minimum by gentle handling, and is usually only temporary. No bad results have been noticed. Intermittent pressure is less annoying than continuous pressure, and neither is as irritating as a solid instrument. Pressure around the glans may be painful. In this, as in the presence of any other unpleasant symptom, judgment must be used. Manipulation should cease for the time, in the face of unpleasant symptoms, at any stage of the operation. The object is to accomplish gradually and progressively the desired end, rather than to demonstrate the physical possibilities of the apparatus. This irritability about the meatus soon passes off, and is less than when gravity alone, as a motive power, is used. That is slower, when successful, and the consequent long-continued pressure more unpleasant.

At first, there may be some nervous reaction, as nausea or vertigo. This rarely persists longer than the first or second sitting.

What advantage the device exhibits lies in the addition of a bulb to a gravity irrigating apparatus for a specific purpose.

To sum up, the writer has noted the following points of excellence in the use of his device:

1. There is greater safety from infection than when instruments are passed into the bladder.

2. The possible pain and nervous reaction are more tolerable than when either intravesical instrumentation or gravity alone, as a motive power, is used.

3. It is more certain than gravity alone, as a motive power. In this last connection an illustrative case may be mentioned. This was one in which the safe introduction of an instrument was impossible because of a false passage, due to previous instrumentation. With this apparatus, on different occasions, a small quantity of liquid was made to enter the bladder, and was voided naturally.

No claim to priority is made, as the writer is not sufficiently versed in the literature on the subject. The device is original with the author, as may appear from the steps in its evolution. It may be useful in other hands.

Leech Fishing.—It appears, says the *Pharmaceutical Journal*, that in meridional Russia, and especially in the innumerable ponds of the basin of the Don and Donetz rivers, the inhabitants gain a remunerative livelihood, though dangerous and disagreeable, in leech fishing. Nothing could be simpler than the method they employ. Bare legged, they tramp about the water; the leeches fix themselves upon the bare flesh and begin to suck. As soon as the fishers reach terra firma, they remove the flabby animals and deposit them in an earthen vessel. It is a painful and weakening operation, and sometimes even fatal, as a recent case amply proves. A woman was fishing in the ponds in the neighborhood of Kamanskaïa, and had already 150 leeches in her vessel. With this on her head she re-entered the water, and was again quickly covered with leeches. Feeling somewhat giddy, owing to loss of blood, she essayed to leave the water. No sooner had she arrived upon the bank than she fell and in doing so had the misfortune to break the earthen vessel. Its blood-thirsty contents being set free lost no time in fixing themselves upon the poor woman, who was in a fainting condition, and unable to defend herself. She was found an hour afterward in a horrible condition and quickly succumbed

Progressive Muscular Atrophy.—Marie D. Khanutina concludes that: (1) In all probability progressive muscular atrophy begins with the appearance of nodules spreading throughout the whole muscular system; it is also probable that in the predominance of these nodules consists the inherited pathological defect of the muscular tissue. (2) Probably the fact, that these nodules, requiring for their multiplication an increased flow of nutritive material, brings about the gradual destruction of the contractile tissue, which perishes in the struggle for nutriment, the nodules in their turn finally perish in this struggle among themselves. (3) Myophagism was proved by Metchnikoff in physiological muscular atrophy in macrocephaly. Marinesco observed it in angiomyopathy, while Levin observed in progressive muscular atrophy the formation of embryonic cells around the nodules and in the protoplasm of their muscular substance. (4) The hypertrophy of separate muscular fibers is not a pathognomonic sign of progressive muscular atrophy, since it has been observed also in atrophic processes of different origin; on the other hand, it cannot be considered as an inherited weakened condition of the muscular system, in view of the many observations proving that it occurs only in such muscles which have already undergone a certain degree of atrophy. (5) The above-named active changes in the muscular substance, in conjunction with the hyperplasia of the connective tissue, would lead one to think that progressive muscular atrophy is a chronic inflammatory process, commencing, probably, with changes in the contractile tissue. (6) The following are some of the details of the pathologic process: (*a*) The disappearance of the contractile tissue, and the decay and the subsequent falling off of the sarcolemma may begin either at the center, or at the periphery of the muscular bundles; (*b*) The fact that the degenerative process may begin at the center of muscular bundles, where there is so little connective tissue in normal conditions, would prove to some extent the primary character of the disease of the contractile tissue, and would tend to disprove the suppositions of some authors that the hyperplasia of the connective tissue brings about the gradual destruction of the muscular tissue; (*c*) With the decay and falling off of the sarcolemma occurs the passive change in form and size of the muscular bundle, which shrinks, the empty spaces being filled up with connective tissue; (*d*) The foci of muscular atrophy occupy neither the whole length nor the whole thickness of the muscular bundle, but attack the same at many points. Thus little bridges of connective tissue are formed, cutting the muscle in its length.—*Russkii Arkhiv Patologii, etc.*

A Case of Occlusion of the Intestines Successfully Treated with Atropine.—P. M. Kalabukhov and M. V. Savin report this case. The occlusion was brought about while riding in a very light vehicle, drilling a young, spirited horse. The symptoms were pain and distention of the abdomen, stercoraceous vomiting, and absolute obstipation unaffected by laxatives. The patient having declined an operation, atropine was tried. The first day, 0.002 sulphate of atropine was injected subcutaneously without result. The second day, 0.005 atropine was injected. The patient fell into unconsciousness with low muttering delirium. The pupils were widely dilated and motionless. The vomiting ceased, but the bowels did not move. The third day, the patient was perfectly conscious; the pupils were normal; after a rectal injection free and copious stools occurred; there was no vomiting, and the pain and distention of the abdomen were much lessened. The general condition improved and the appetite returned. On the fourth day, a free movement occurred after rectal injection. After this there was no further need of rectal injections; a regular, voluntary movement occurred daily, there was no vomiting and the distention of the abdomen was very slight. Upon palpation, slight pain was complained of in the region of the cæcum, but the general condition was good, and the patient [illegible]—*Vrach.*

Epistaxis; Its Causes and Treatment.—MacLeod Yearsley classifies the causes of nosebleed in four groups, viz., traumatic, nasal diseases, constitutional conditions, and vicarious. In the treatment of such cases as will not yield to domestic remedies, the common-sense way is to find the source of the hemorrhage and treat it, making a careful search by means of reflected light and a nasal speculum. Should bleeding interfere with the investigation, it is proper to plug the nostril and make a further search later. Strips of antiseptic gauze carried as far back as possible or Cooper Rose's epistaxis bag may be used. Plugging the posterior nares need not be undertaken in these days. Plugs should not be retained more than from twenty-four to forty-eight hours. In removing gauze plugs, gentleness must be observed, and it is often useful to introduce some bland oil and allow the plug to soak it up before attempting removal. Hemorrhage from simple septal ulcers requires treatment by the galvanocautery. In all cases of epistaxis it is well to bear in mind the frequency of nasal bleeding as a local manifestation of some general condition, and to take measures for constitutional treatment accordingly.—*Treatment.*

The Diprogonopolos Grandis: a New Tape-worm.—J. Kurimoto describes a tape-worm which is larger than the Tænia solium or the mediocanellata, being about ten and a half centimeters broad and ten meters long. Its uteri are in two sets parallel to each other; the breadth of the individual joint far exceeds its length. There are deep furrows on both its dorsal and abdominal surfaces, and its ovum differs in shape from that of other tape-worms. In the ordinary tape-worm, new segments are produced by the head, the segments at the distal point being the most mature, but in the new variety each segment divides, and the old and the young alternate. The symptoms caused do not differ from those due to the common species, except in being more intense. Treatment is the same.—*Tôkyô Sei-I-Kwai Medical Journal.*

Mortality in Russia.—According to Russian journals, there is no country of the world where the death rate is so high and the average of human life so short as in Russia. The St. Petersburg *Vedomosti* is responsible for the statement that the average length of life in that country is but twenty-nine years. "The mortality in St. Petersburg is higher than anywhere else in Europe, Constantinople alone excepted. The death-rate percentage in London is seventeen per 1,000, in St. Petersburg it is forty per 1,000. Moscow sometimes even beats this enormous rate of mortality. Among the reasons that increases the death rate in St. Petersburg, infectious disease occupies a prominent place.

The Medical Schools of the United States.—A late number of the *Journal of the American Medical Association* gives a brief description of the 155 medical schools of the United States. It is claimed by all but two of these that a four years' course is compulsory. Twenty-six thousand one hundred and forty-seven students and 5,058 teachers were registered in these colleges in July, 1901. Five thousand four hundred and forty-four degrees of M.D. were conferred during the past year. Canada has but twelve medical schools.

Young Sightseers.—Berlin, says *Tit-Bits*, has a child exchange. The poorer people of the city who cannot afford outings send their children to country peasants and receive in return for an equal length of time peasant children who want to see the city. The plan has worked so well that the charitable German women who originated it would like to extend it. There is even talk of exchanging children between neighboring countries, so that they will gain still more valuable experience.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, November 30, 1901.

A PROPOSED INCREASE IN THE POWERS OF THE ARMY MEDICAL DEPARTMENT.

A PAPER entitled "Preventable Disease in the Army of the United States—Cause, Effect, and Remedy," lately read by Major W. O. Owen, Surgeon, United States Army, before the Academy of Medicine at Cincinnati, and published in a recent issue of the *Journal of the American Medical Association*, has elicited much comment from medical journals, and from such publications as the *Army and Navy Register*, which devote their columns to matters of military interest. The daily press also gave much space to notices of Major Owen's paper, apparently not so much from the practical importance of the questions involved, but because of the supposed criticism by the author of certain line officers of high rank. The criticisms made in the paper referred to—and they are made in very plain language—are, however, obviously not directed against individuals, but against the defects of an existing system.

Briefly, the author desires the enactment of legislation by Congress which will fix the responsibility for sanitary deficiencies among troops, and provide a penalty therefor; and which will also secure to the Medical Department the right to its self-control, to supervise and administer the transportation of medical supplies, instead of relying upon the Quartermaster's Department, as at present, for the performance of this duty. He believes that the Medical Department should be given complete control of all matters having to do with the sanitary care of troops, and calls attention to the fact that, while paragraph 1393 of Army Regulations makes it a duty of the medical officer to point out sanitary errors and to suggest measures for their correction, there is no clause or provision to prevent his commanding officer from treating his suggestions "with good-natured indifference or worse." The assumption of this attitude by commanding officers he regards as not infrequent, and he cites numerous instances which occurred during the war with Spain to show the lamentable results which followed such a policy by the line officer in authority.

It will be generally admitted that many of Major Owen's contentions are not without truth, but he apparently makes the mistake of assuming that disregard by the commanding officer of the surgeon's recommendations is the general rule rather than the exception in the United States Army. He also overlooks the beneficial and saving influence of the clause in the paragraph of regulations already cited, which requires the commanding officer to indorse his objections fully on the medical officer's report, "if he deem the action recommended impracticable or undesirable." The report, with the indorsement thereon, is then forwarded by military channels to higher authorities, by whom it is considered and, if necessary, acted upon before its final receipt by the Surgeon-General. If the latter deem the matter of sufficient importance, a decision from the Secretary of War may be called for in the case. This system, in time of peace, undoubtedly results in a careful consideration of the surgeon's recommendations by the commanding officer, who would naturally hesitate, through an arbitrary or unwise decision in the matter, to lay himself open to discipline by a superior reviewing authority. In local commands—and in the great majority of instances—the surgeon is thus insured a hearing by higher authority. With an independent army in the field, however, the general officer in command has the power to ignore and stifle the recommendations of his chief surgeon, who, in this particular instance, cannot appeal to higher authority without committing a military offense, even though he, and not the commanding general, would be held responsible by public opinion for an unnecessary sacrifice of the lives and health of troops; and it is stated by the writer referred to that an instance of this sort occurred in one of the large camps of 1898, where, had the sanitary recommendations been followed, the prevalence of typhoid fever would have been materially diminished. One section of the bill proposed by Major Owen provides for the trial by court martial of any subordinate officer, medical or line, by whose carelessness or inattention to duty any unusual outbreak of disease shall have arisen. This plan may be well enough so far as it goes, but it obviously does not reach such a case as has just been quoted. If provision were made for an investigation to determine the responsibility in a case of this kind, the existence of such a provision, even if of no immediate value in a given instance, would have a cautioning effect upon commanding officers of high rank, and would add considerable weight to any recommendations which might be made by their chief surgeons. To secure such a result, however, the necessary additions can be made to army regulations by the Secretary of War, without the necessity for Congressional action.

It has been objected with much reason that the official channels through which sanitary recommendations are obliged to pass, though satisfactory in time of peace for troops in well-ordered military posts, require the consumption of too much time to permit of properly meeting the sudden sanitary emergencies which not infrequently arise among large bodies of troops in the field; that, before the report and recommendation with respect to existing conditions can finish its tedious round and return with the action of higher authority, the damage has been done, general infection has taken place, and an epidemic is perhaps already manifest. This is undoubtedly the case. The problem can be simply solved, however, by adding a paragraph to army regulations, providing that, with troops in the field, the senior surgeon or a designated sanitary inspector may have delegated authority to act in emergency sanitary matters, and issue any necessary orders in the name of the commanding officer; the orders so issued being, of course, subject to reversal by the commanding officer, and

the medical officers concerned being held accountable by him for any misuse of such delegated authority. Such a regulation could be promulgated without Congressional action, and would obviously cover the control of all emergency sanitary matters, save where the commanding general himself is directly concerned.

Finally, as the most important step toward the sanitary improvement of our army, a course of instruction in the principles of hygiene and sanitation should be given at West Point, so that the commanding officers of the future, while not necessarily required to be experts in such matters, will have sufficient knowledge of these subjects themselves readily to recognize the grosser sanitary faults, and will be able better to appreciate the importance of the recommendations made by the sanitary experts whose special duty it is to investigate and keep themselves informed concerning such matters. Line officers, like medical officers, are earnest in their endeavors to preserve the health of the troops under their command, and it is ignorance, rather than indifference, which creates a majority of the obstacles now and then encountered by the sanitary officer. Instruction in matters of hygiene to the cadets at West Point is the present greatest need of the United States Army, and the energies of the medical profession and country at large would be devoted to much better advantage in securing from Congress the addition of a suitable course in the principles of hygiene at that institution, rather than in attempting to force the passage of the legislation proposed by Major Owen, which can be counted upon at once to excite such unanimous and active hostility from line officers as to insure its own defeat. Something may certainly be done toward the improvement of sanitary conditions, but not in the manner or to the extent proposed by Major Owen. Under no circumstances will military conditions tolerate any division of the powers of the commanding officer; and, so far as he himself is concerned, the recommendations of his surgeon must be advisory, even though he may clothe the latter with delegated authority over sanitary matters affecting his subordinates. The main thing, after all, is to be secured by the early education of line officers in sanitary matters, so that they may be able to appreciate the practical importance of their sanitary advisors, and realize that these recommendations are based upon an accurate knowledge of well-demonstrated scientific facts, and are not mere "fads" of the meddlesome and irresponsible.

With respect to Major Owen's contention, that the Medical Department should control the transportation of its sick and wounded, material and supplies, it is safe to say that every medical officer of the army is in hearty sympathy. In the war with Spain, the insufficiency of equipment and supplies at certain points for the care of the sick and wounded provoked much unwarranted criticism of the Medical Department, when the facts were that another department, whose duty it was to transport these supplies to the places where they were needed, had failed to do so. The Medical Department should be given complete control of the transportation of its own supplies, and then be held to a strict accountability for results.

THE DESTRUCTION OF MOSQUITOS.

Bulletin No. 6 of the Hygienic Laboratory, U. S. Marine Hospital Service, just published, contains much valuable information with respect to the destruction of mosquitos by means of formaldehyde and sulphur dioxide, based upon a series of experiments on this subject made by passed Assistant Surgeon M. J. Rosenau, U. S. Marine Hospital Service.

Accepting the fact that the mosquito is known to transmit the infection of yellow fever, malaria, and filariasis, Dr. Rosenau undertook to determine the practical value as insecticides of formaldehyde gas and sulphur, imitating the conditions found in actual practice in so far as they were compatible with accurate control of the results. The mosquitos used were good specimens of *Culex pungens* reared in the laboratory, with the sexes in about equal proportions. In some of the experiments, the insects were permitted to seek shelter from the gases in folds of clothing and in heaps of cloth and loose paper, thus avoiding the stronger percentages of the gas; and a remarkable self-protecting instinct in this direction was observed. In other experiments, the insects were exposed under definite conditions, contained in small pill boxes, the open tops of which were replaced by gauze netting, so as to determine exactly the amount of protection required to prevent the penetration of the gas to the mosquitos in sufficient strength to kill them. By the use of these boxes, it was also possible to compare the germicidal with the insecticidal powers of the gases used, cultures of bacteria being exposed in similar boxes, under identical conditions, upon slips of paper. For this purpose both sporulating and non-spore-bearing bacteria were employed. When exposed directly to formaldehyde gas produced by any of the methods commonly used for purposes of disinfection, mosquitos were found to be killed in a few minutes. The conditions necessary to insure this direct contact, however, cannot always be obtained in actual practice. Mosquitos were found to resist the weaker percentages of formaldehyde gas, and rooms are frequently not tight enough to obtain the necessary degree of concentration. Methods which liberate a large volume of the gas in a short time are more certain than the slower ones. With free insects under ordinary room conditions, disinfection is much more difficult to obtain in the case of mosquitos than against bacteria, since the former seek to escape from the irritating gas and hide in bedding, folds of clothing, draperies, and out-of-the-way places, where formaldehyde does not penetrate in sufficient strength to secure their destruction. The gas is polymerized in the meshes of fabrics, and large quantities of it are neutralized by the organic matter contained in woolens and other fabrics. An analogy was found between the strength of the gas and the time of exposure necessary to penetrate the fabric and kill the mosquitos, and the time and strength necessary to penetrate, in order to kill the spores of the bacteria.

Mosquitos have a lively instinct in finding cracks or chinks where fresh air may be entering a room, or where the gas is too diluted to cause their destruction. They were found, under these circumstances, to escape through extremely small openings, some of the smaller varieties of insects passing through a wire screen having twelve meshes to the inch. Formaldehyde, therefore, cannot be trusted to kill all the mosquitos in a room which cannot be tightly sealed, and for this reason must be regarded as, in practice, but a feeble, uncertain, and unsatisfactory insecticide. On the other hand, sulphur dioxide was found to be

very efficacious in this respect, and very dilute atmospheres of the gas will quickly kill mosquitos. Six ounces of sulphur burned in a room of 500 cubic feet capacity readily destroyed mosquitos, even when protected under several thicknesses of cloth. Under the same conditions, the vitality of the bacterial controls was unaffected. Sulphur dioxide is also quite as efficacious when dry as with a moist atmosphere, whereas the dry gas has little effect upon bacteria. Contrary to formaldehyde, sulphur dioxide has excellent penetrating powers for insecticidal purposes; even in very dilute proportion killing mosquitos protected by four layers of toweling in an hour's time. Sulphur dioxide is therefore to be regarded as by far the best gaseous disinfectant for use in the destruction of mosquitos.

It is interesting to note in connection with this subject, that, while both formaldehyde and sulphur dioxide have been much used as insecticides by the army medical officers in Cuba in their efforts against yellow fever and malaria, reliance has lately been had upon the fumes of pyrethrum powder, one pound of which is burned for each one thousand cubic feet of room space. The insects, while not killed, are stupefied by the fumes and fall to the floor, whence they are subsequently swept up and burned. This method avoids both the uncertainty attendant upon the use of formaldehyde and the destructive results upon fabrics and metal objects which are liable to result from the use of sulphur dioxide.

Care in Respect to Drinking Water in the Philippines.

In view of the large number of cases of dysentery occurring among the troops in the Philippines, General Chaffee has directed the strict enforcement of additional sanitary measures recommended by the chief surgeon. Hereafter commanding officers will require that canteens and all other vessels containing water for drinking purposes be thoroughly scalded every two weeks, and always after the return of troops from field service, special care being taken to keep the stoppers clean. Soldiers on the march are also enjoined to practise self-denial in regard to drinking water which may be found along the roadside. "It is a fact," says the order, "demonstrated by long experience of old soldiers, that if water is drunk during the first few hours of the march, the thirst will continue during the entire day, and necessitate the drinking of a large amount of water during that period wherever it can be found. Every soldier should think of the effect which free use of water is liable to produce before drinking all kinds, which, in the opinion of the chief surgeon and the medical officers generally of this division, is a very large factor in producing the various kinds of dysentery incident to this command."

Colonel Charles R. Greenleaf, Assistant Surgeon-General U. S. A.

Colonel Charles R. Greenleaf, Assistant Surgeon-General, who is about to retire for age after more than forty years of service, and who was Chief Surgeon of the armies in the field during the war with Spain, and later Chief Surgeon in the Philippines, is a candidate for promotion to one of the coming vacancies among the brigadier generals in the line, to enable him to retire with the higher rank to which his long and valuable services fairly entitle him. His claims to such promotion were strongly supported in a recent editorial in the *Army and Navy Register*. Colonel Greenleaf was twice recommended—once by General Miles and once by Surgeon-General Sternberg—for promotion to the grade of brigadier-general of volunteers at the close of the war with Spain, for his most efficient services in the field throughout that war, but failed to receive such appointment—though similar appointments were given to officers of the paymasters', quartermasters', Commissary, Judge-Advocates', and other "non-combatant" departments, though in at least one instance the officer so promoted had no field service whatever.

The Health of the King of Great Britain.

The Medical Press and Circular, a journal distinguished among its British medical contemporaries by its outspokenness, is persistent in its endeavors to obtain from authentic sources a true and responsible statement with regard to the state of King Edward's health.

Rumors have been current for some time, and especially in certain American lay journals, that all is not well with the ruler of Great Britain, and it has even been asserted that he is suffering from a disease of the throat which has already rendered necessary operative measures. The principal journals of Great Britain, both lay and medical, have practised the rigid reserve which is customary in that country where royalty is concerned. Such methods are dictated, not only by prudence and nice feeling, but by reasons of state. However, the *Medical Press* takes the ground that it would be better for the public welfare if the real facts of the case were published, and argues that by such action the anxiety of the people would be allayed, or, if the most unfavorable accounts were substantiated, that the situation could be more boldly faced than if they were kept in ignorance up to the last.

Renal Disease and Insanity.

The *Practitioner* for November, among other able articles dealing with kidney affections, contains one by Dr. Theo. B. Hyslop which treats of the oft-asserted connection between diseases of this class and insanity and statistics. Numerous authorities and statistics are quoted by the writer to show that the frequent occurrence of various forms of renal disorder must be looked upon as something more than a coincidence. H. C. Bristowe, for instance, found that out of 75 cases of general paralysis only nine were free from renal troubles, fifty-one cases had well-marked granular kidneys, and fifteen were affected, but in a less degree. The same investigator observed that out of a total of 3,446 cases of insanity 48.8 per cent. had renal disorder of some nature, while of 266 cases of general paralysis, 183, or about 68.8 per cent., showed signs of renal trouble.

Regarding the matter also from a clinical standpoint, one cannot avoid being struck by the fact that in many mental states, albumin is more often than not present in the urine.

Dr. Hyslop, from a consideration of the question, judged by his own experience, and that of other observers, concludes that renal disease is associated with insanity in two ways: (1) Acute transient delirious mania, an acute toxæmia, or uræmic insanity, and (2) A progressive cerebral degeneration, with chronic renal disorder as the primary cause.

A Joke on the Learned Doctor.

The Berlin correspondent of the *British Medical Journal* relates a really very amusing event which occurred to a grave and serious German professor.

In the *Zeitschrift für klinische Medizin*, edited by Professors von Leyden and Klemperer, Dr. Speck publishes an article reviewing and criticising modern

therapeutic fads, such as the "light treatment," etc. In the course of his diatribes against what he thinks present-day futile methods of treatment, he makes the new "darkness treatment" the object of his most bitter invective and most biting sarcasm.

Dr. Speck read in a paper named the *Davoser Blätter*, said to be published by Drs. Rile and Herz, a long and minute account of this latest mode of successfully treating tuberculosis, discovered by them. So aroused was Dr. Speck by the publication, according to his idea of another and most impudent attempt to gull a too confiding public, that he quotes in the pages of the prominent German medical journal details of the cure, advertised by Drs. Rile and Herz, which were as follows: A sanitorium for consumptives in the catacombs of Syracuse, 150 meters below the surface of the earth, where the patients are kept for months without the light of day, with the astonishing result of 83 per cent. cures and 17 per cent decided improvements; he further quotes, but with withering indignation, "the scientific explanation of this treatment, which is offered, namely, the increased blood pressure, and the fact that the mole is notoriously free from tuberculosis."

Unfortunately, Dr. Speck was decidedly lacking in a sense of humor, and failed to notice that the signatures appended to this singularly lucid and convincing article were "Dr. A. P. Rile and Dr. S. C Herz (Scherz, German for joke), and in addition that it was dated from Fanfaronnata.

It goes without saying that seldom is an April joke brought off so successfully as the ingenious concoction of nonsense published in the *Davoser Blätter*.

A Vaccination League in England.

A vaccination league has been recently inaugurated in England. This league has been established for the purposes of educating the masses with regard to the benefits derived from vaccination, and to spread better understanding among the general public of the advantages arising from preventive medicine and practical sanitation. The league is composed of several prominent laymen, and of a large number of the foremost medical men of Great Britain, including Mr. Jonathan Hutchinson, Sir Alfred Garrod, and Professor Charles Stewart.

The scheme is greatly to be commended, and should do much to offset the active propaganda of the views of the antivaccinationists, who lose no opportunity to depreciate the beneficial effects of Jenner's discovery, and who unblushingly play upon the ignorance of a large majority of the population. The league will endeavor to disseminate the truth, by means of literature and lectures.

Hygiene of Churches.

Those cognizant of the condition of churches on the Continent of Europe will not be surprised at the report just made to the Paris Academy of Medicine by M. Reminger, sub-director of the Pasteur Institute at Constantinople. For months, this gentleman has been investigating the hygienic surroundings of many churches, and he has found that "most of them are far from healthful, are lacking in provisions for ventilation—a fact which largely accounts for the frequent fainting fits of many of the congregation." This evil is, however, by no means confined to the churches of Europe. The United States possesses many places of worship which are responsible for many a case of serious illness, and especially of pneumonia and diseases affecting the respiratory organs. Defective ventilation of churches is quite an old story in this country, and the MEDICAL RECORD has done its share in calling attention to the fact.

News of the Week.

The Second New York State Conference of Charities and Corrections was held in this city last week, under the presidency of Mr. Robert W. De Forest, about six hundred delegates being in attendance. Many subjects were discussed and papers read, among those arousing considerable interest being the question of state and municipal sanatoria for consumptives. This was discussed by Drs. John H. Pryor and E. Park Lewis of Buffalo, and Alfred Meyer and S. A. Knopf of New York, and Messrs. Frederick Almy, Homer Folks, and Samuel D. Levy. The care of the mentally defective was another of the subjects of especial medical interest that came before the conference.

Is Tuberculosis a Loathsome or Dangerous Disease?—A man who arrived here on November 9, with his wife and child, was found by the immigration officials to have tuberculosis, and under the recent ruling that immigrants suffering from this disease come under the head of "persons suffering from a loathsome or a dangerous disease," he was ordered sent back to Ireland, from which country he came. He has relatives, however, in Philadelphia, who have obtained a writ of habeas corpus, and a test will be made for the legality of this ruling.

Death of a Centenarian.—There died last week in Utica a man named Abraham Ephraim Elmer, who was thought to be nearly 120 years old. According to the record in the family Bible, he was born in Warren, Herkimer County, on January 26, 1782. He was a shoemaker, and worked at his trade steadily until he was over a hundred years old. He was a hard worker, but lived much in the open air, walking ten miles when he was 124 years old. He was not a hard drinker, but took a moderate amount of whiskey daily; he had chewed tobacco steadily since he was ten years old. He was one of a family of fifteen, all of whom he survived, and had eleven children, five of whom are dead. He was survived by six sons, one daughter, twenty-five grandchildren, nine great-grandchildren, and three great-great-grandchildren.

Police Surgeonship and Municipal Civil Service Commission.—An examination for the position of Police Surgeon will be held by the Civil Service Commission, 346 Broadway, beginning December 9, 1901. The subjects of the examination are technical knowledge and experience. Applications should be filed as soon as possible in order to secure admission to the examination. For applications apply to Lee Phillips, Secretary.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy for the week ended November 16, 1901: November 8.—Pharmacist J. Cowan ordered to the Boston Navy Yard. November 11.—Surgeon G. T. Smith, detached from the *Amphitrite* and ordered to the *Puritan*, when commissioned. P. A. Surgeon R. S. Blakeman, detached from Naval Hospital, Norfolk, Va., and ordered to the *Hartford*. Asst. Surgeon E. G. Parker, detached from the *Hartford* and ordered home and to wait orders, on relief reporting. November 13.—Asst. Surgeon W. L. Bell, detached from the Naval Hospital, Cavite, and ordered home to wait orders. Asst. Surgeon L. W. Bishop, detached from the *Independence* November 25, and ordered to Naval Hospital, Cavite, P. I. Asst. Surgeon H. C. Curl, detached from the Naval Hospital, Cavite, upon reporting of relief, and home to wait orders. Asst. Surgeon G. M. Mayers, detached from the Pensacola Navy Yard and ordered to the Naval Hospital, Cavite,

P. I. November 14. P. A. Surgeon C. M. DeValin, detached from the Naval Hospital, Portsmouth, N. H., and ordered to the *Rainbow*. P. A. Surgeon S. G. Evans, ordered to the Naval Hospital, Portsmouth, N. H. Asst. Surgeon W. H. Bell, detached from the *Franklin* and ordered to the Naval Hospital, Norfolk, Va.

A Swindler.—Pinkerton's National Detective Agency advise us of the operations of a swindler who is forging the names of physicians in different cities and towns as indorsements to bogus checks passed by him upon banks in which the physician whose name is forged has an account. The swindler's modus operandi is as follows: Calling upon physicians, he introduces himself as an agent for an association which contracts to supply its members with medical books at from 20 to 30 per cent. less than the regular rate, and soliciting a membership fee of one dollar. As an inducement to sign the contract, the swindler waives the membership fee, obtaining the signature of the physician solicited, at the same time requesting a bank as reference. In this way the swindler gets his victim's signature and the name of the bank in which he has an account. Several hours later he appears at the bank named with a fraudulent check requesting payment. Upon being refused payment, he states that he will have a physician indorse the check (naming the physician who is a depositor and whose signature he had previously obtained in the method described above). The bank officials usually state that such an indorsement will be accepted. The forger then leaves the bank, forges the name of the physician selected earlier in the day, and on presenting such check again at the bank, is usually accommodated with the amount for which it is drawn. The swindler is a rather dapper-looking young man of about thirty years of age; five feet eight inches tall; weighs about 140 pounds; is of slender build; has light complexion, light hair, blue eyes, rather large nose, and is usually clean shaven. It is suggested that if this man calls upon any one who has read this warning that he evince no suspicion, but furnish the so-called solicitor with his signature and bank reference, and immediately notify the bank where he has his account, advising them of the man's scheme.

College of Physicians of Philadelphia—Section on General Medicine.—At a stated meeting held November 11, Drs. Sailer, Pfahler, and Shields reported "Two Cases of Aneurysm of the Descending Portion of the Arch of the Aorta" in which pain in the chest and inequality of the pulses were prominent symptoms, and the diagnosis was established by means of fluoroscopic examination and skiagraphy. Dr. Augustus A. Eshner exhibited "A Specimen of Green Urine" from a child that had taken a pill said to contain a combination of palmitic acid and iron. A similar peculiarity was observed in a second child that had also taken such a pill. It was thought that the condition was due to some aniline pigment contained in the pill, such as methyl-green or methylene blue. Dr. Eshner also reported "A Case of Acromegaly." The patient was an iron-worker, thirty-two years old, with large hands and feet and nose, a projecting and enlarged lower jaw, prominent malar arches and overhanging brows, dorso-lumbar kyphoscoliosis, but without ocular changes or other evidence of disease of the pituitary body. Dr. Alfred C. Croftan presented a communication entitled "Experimental Investigation into the Causes and Treatment of Diabetes Mellitus." He showed that the leucocytes of the blood, apart from the serum, possess a glycolytic property, and that this is dependent upon a body closely resembling, if not actually identical with, trypsin. It was thought that the deficiency of this ferment in association with disease of the pancreas is responsible for the glycosuria that results under such circumstances. The therapeutic deduction from these observations is the introduction into the circulation of trypsin, or of white blood corpuscles, or of blood itself.

Trypsin, however, cannot be employed in this manner, as it gives rise to toxic symptoms. It was pointed out as an interesting fact in this connection that glycosuria sometimes disappears on the development of some acute infectious disease.

The Anglo-American Nursing Home at Rome.—The Anglo-American Nursing Home at Rome was founded two years ago for the purpose of receiving English-speaking patients, of sending out trained nurses, and of providing two free beds for the use of the many poorer English residents in Rome, such as teachers and students, who are not able to afford the expenses of illness in their own homes or lodgings. The home has already proved of great value to many English or American travelers who have been overtaken by sickness in Italy. Nurses are sent from the home to other parts of the country, and have already gone as far afield as Florence, Naples, and Sicily. There are twelve nurses now upon the staff, but a large number of applications, on behalf of invalids requiring nurses, have been per force refused. The home was founded by a number of English, American, and Italian residents, and is managed by an English matron under the control of a general and house committee of well-known persons. It is hoped that in time the home may become self-supporting, and that it may not only supply a hospital for the sick, but also a convalescent home for invalids in Rome, and that the nursing staff may be enlarged to meet the great demand now made upon its services.—*British Medical Journal.*

Compulsory Vaccination.—An instructor in the Philadelphia High School for Girls has been dismissed for failure to comply with the direction of the Board of Education that all school employees should be revaccinated. The request of an instructor in the Philadelphia Central High School for Boys that he be excused from being revaccinated on account of the presence of lymphadenitis was not acceded to.

An Infant Prodigy.—From Wilmington, Del., comes the report that a child, twenty-one months old, the son of a teacher in a local academy, is able to read. When given a set of toy blocks recently, it is said, the infant arranged them so as to form words. At another time he was found on the floor with a newspaper in his hands, apparently reading. When questioned, the child actually appeared to know what the paper contained.

Advanced Requirements in Ohio Medical Schools.—At a meeting held in October, the Ohio State Board of Medical Registration and Examination decided that on and after July 1, 1903, the standard for examination for entrance to Ohio medical colleges shall be equivalent to a four years' high school diploma, and that the entrance examiners shall arrange the subjects for such examination in accordance with such standard.

The Utah State Medical Society.—At the annual meeting of this society, held at Provo, in October, the following officers were elected: *President*, I. A. E. Lyon of Salt Lake; *First Vice-President*, Philo E. Jones of Salt Lake; *Second Vice-President*, R. E. Steele of Lehi; *Treasurer*, J. M. Harrison of Salt Lake; *Secretary*, George E. Robinson of Provo.

The next annual meeting will be held in Salt Lake City.

The Wyoming State Medical Society.—At the fifth annual meeting of this society, held at Evanston in October, the following officers were elected: *President*, G. G. Verbryck of Cambria; *First Vice-President*, F. H. Harrison of Evanston; *Second Vice-President*, W. C. Burk of Rock Springs; *Third Vice-President*, W. A. Wyman of Cheyenne; *Secretary*, C. H. Solier of Evanston; *Treasurer*, J. L. Wicks of Evanston. The next annual meeting will be held at Cheyenne.

The Refugee Camps in South Africa.—Referring to the excessive mortality among the Boer reconcentrados, Lord George Hamilton, the Secretary for India, says that it is a matter of great concern to the government, and that everything that sanitary science can suggest has and will be done. The British officers, he says, are greatly hampered by the callousness to all hygiene of many of the women in the camps, and of their tendency to have recourse to various domestic and quack remedies of the most detrimental and dangerous character.

King Edward's Health.—A dispatch to the *Sun* says that Sir Frederick Treves, whose dignities include the office of surgeon to the King, in the course of a speech in London on November 20, referred to the recent tales in regard to his Majesty's health as foolish and wicked reports. He added that it was a pleasure to him to be able to state that King Edward never enjoyed such excellent health as at the present time.

The Tri-State Medical Society.—At the thirteenth annual meeting of the Tri-State Medical Society of Tennessee, Georgia, and Alabama (the original, we believe, of the many Tri-State societies now flourishing), held in Nashville, October 8 to 10, the following officers were elected: *President*, J. C. LeGrand of Birmingham, Ala.; *First Vice-President*, Pugh U. Brown of Troy, Ala.; *Second Vice-President*, Wm. P. Harbin of Rome, Ga.; *Third Vice-President*, J. C. Wilson of Rockwood, Tenn.; *Secretary*, Frank Tester Smith of Chattanooga, Tenn.; *Treasurer*, Geo. R. West of Chattanooga, Tenn. Birmingham, Ala., was chosen as the next meeting place.

Dinner to Dr. T. Gaillord Thomas.—On the evening of Thursday, November 21, the friends of Dr. Thomas met at dinner at Sherry's to commemorate the seventieth anniversary of their guest's birth. Dr. Thomas was born on Edisto Island, near Charleston, S. C., on November 21, 1831. He was graduated from the Medical College of the State of South Carolina in Charleston in 1852, and for sometime thereafter was resident physician at Bellevue Hospital in this city. Later he served in a similar capacity in the Rotunda Hospital, Dublin, Ireland. Many prominent physicians and surgeons attended the dinner. Dr. J. W. McLane presided and acted as toastmaster. Covers were laid for three hundred. Among those who spoke were Dr. S. Weir Mitchell, Judge Howland, Drs. W. H. Welch of Baltimore, and Shattuck of Boston, and the Rev. Dr. D. H. Greer of this city.

The State Consumptive Hospital.—The Board of Trustees of the State Hospital for the Care of Consumptives, after inspecting many sites, have decided that Ray Brook, on the west side of the Adirondacks, is the best suited for the proposed institution. While Governor Odell has not finally approved of the selection of this site, it is said that he regards it as the most available of those inspected.

The Violet Cure for Cancer.—A London paper recently printed a story of a woman who was suffering from a laryngeal growth which had been pronounced cancerous. Death appeared imminent when a neighbor recalled an old wife's remedy of which she had heard in childhood. This remedy was to take a handful of fresh green violet leaves, put them in a pint of boiling water, cover them and let them stand for twelve hours; then strain off the liquid, dip a piece of lint into the heated infusion, apply the wet lint hot, cover the lint with oil silk and change whenever it became dry and cold. The infusion should be made fresh every alternate day. The story continues that this remedy was applied with almost instantaneous effect, and that the patient within two weeks was seemingly cured and able to travel. The florists at least benefited by this report, for the demand for violets suddenly became so great that the price rose to almost fabulous figures in the flower markets, and none but the richest can now wear violets for ornament.

Obituary Notes.—Dr. DWIGHT WASHINGTON DAY of Eau Claire, Wis., one of the best-known physicians in that State, fell dead on November 18, while reading a paper at a medical meeting. He was born in New York State in 1841, and was graduated from the medical department of the University of Buffalo in the class of 1861. He served during the Civil War as surgeon in the Union Army, and then settled in Wisconsin.

Dr. JAMES P. JACKSON of Kansas City, Mo., died at his home in that city on November 22, at the age of fifty-seven years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1873, and was professor of surgery in the University Medical College, Kansas City. He was prominent in railway surgery, having established the Missouri Pacific Railroad's first hospital at Washington, Mo. He also organized the Wabash and Missouri Pacific hospital service in Kansas City. He was a member of the International Association of Railway Surgeons.

Dr. J. M. RICE of Worcester, Mass., died on November 11, at the age of seventy-four years. He was born in Milford, N. Y., in 1827, and was graduated from the Castleton Medical College in 1853. During the Civil War he served as surgeon in the Union Army.

Dr. JOHN HAMMOND LOVATT died suddenly at his home in Florence, Kan., on November 23. He was born in Yorkshire, England, in 1841, and was licensed to practise by Queens Hospital and Sydenham College, Birmingham, in 1861. He was engaged in private practice until 1870, when he became a surgeon in the British army. At the end of five years he resigned his commission, and in 1885, came to America, and settled in St. Louis, but in 1887 removed to Florence, Kan.

Dr. WM. FISHER NORRIS died of pneumonia at Philadelphia on November 18 at the age of sixty-two years. He was graduated from the medical department of the University of Pennsylvania in 1861, and two years later was appointed assistant surgeon in the U. S. Navy, being placed during the year 1864 in charge of the Douglas General Hospital in Washington, D. C. He was the first exclusive practitioner of ophthalmology in Philadelphia, and he was in 1876 elected professor of that branch in the University of Pennsylvania. For many years he was one of the surgeons to Wills Eye Hospital. He was also president of the American Ophthalmological Society from 1885 to 1889, and at the time of his death he was president of the board of managers of the University Hospital, and a manager of the Mutual Assurance Society

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

WEATHER AND PUBLIC HEALTH—MEDICAL SOCIETY—SOUTH AFRICAN TYPHOID AND INOCULATION—HARVEIAN ORATION—ENDOWED LECTURESHIPS AT THE COLLEGE OF PHYSICIANS—DR. GLOVER RESIGNS FROM MEDICAL COUNCIL—DEATHS OF MR. SPENCER SMITH AND DR. A. HUGHES BENNETT.

LONDON, November 8.

A WEEK of such weather as we seldom suffer! Five days of fog, two of them the real London specialty, worse than the rising generation has witnessed, though their elders remember such; traffic delayed or suspended with sad results! Between 200 and 300 accident patients have been taken to the hospitals—many serious, some fatal. At the docks, men have fallen in and been drowned and a number are missing. On Wednesday evening, cold was intense, and the next morning the registering thermometer showed that we had had our first sharp winter frost. It is a mee bright day to-day, but every one is suffering from catarrh or other trouble of the respiratory organs, so that doctors are excessively busy when well enough themselves to attend to their patients. We talk of the London special fog, but other towns report an equally disastrous condition, as do both sides of the channel.

Smallpox steadily increased. By Wednesday, the number under treatment had reached into the third hundred.

One of the Liverpool plague patients, a child of seven, died yesterday. The other two are pronounced out of danger. No fresh cases have occurred.

South African experience of typhoid was well represented at the meeting of the Medical Society. Drs. A. Elliott and J. W. Washbourne contributed a paper in which they analyzed 262 cases in the Imperial Yeomanry Hospital at Deelfontein and compared their home statistics and those of the Johns Hopkins Hospital. They came to the conclusion that the type of the disease in South Africa is practically the same as that met with in America and England, and that inoculation is of little practical value. The mortality and incidence of relapse were much the same as in other epidemics. In 156 patients who had not been inoculated, the mortality was 10.7 per cent., while it was 10 per cent. among twenty-five who had been inoculated. Adding to these cases recorded at other hospitals, they found the mortality among 120 inoculated patients was 7.4 per cent. and among 556 not inoculated 10.9 per cent. They did not consider this difference pointed to marked beneficial effect of the proceeding. With regard to its influence on incidence, fifty-nine of their staff were inoculated, of whom four took the fever; twenty-five were not, of whom four also took it. The four of the latter were dressers, and younger than the rest of the staff. Adding to these various other statistics, they found among 224 inoculated persons an incidence of attack of 11.4 per cent. against 14.6 per cent among 157 not inoculated.

Dr Cayley considered the evidence in favor of inoculation strong enough to make it desirable that it should continue to be used.

Professor Wright admitted the results were not so good as those in India, but held that some benefit was obtained in the worst environment. A most important question was how long the patient had been inoculated, as there was a negative result which often followed an excessive dose. The injection only protected for a short time, and he quoted statistics in favor of being inoculated twice. The dose had to be carefully adjusted, and he now gave a small dose and repeated it, so as to avoid the negative phase. In some cases, the injection gave no protection, as shown by the bactericidal property of the blood.

Surgeon-General Henry Cayley quoted the statistics of the Scottish Hospital, South Africa. Of the fifty-four persons of the first section, all except three were inoculated twice, two once, and one not at all. Not one of the fifty-four took typhoid, and twenty-five were at the most susceptible age, being medical students from nineteen to twenty-four years. In the second section, out of 102 persons, seventy-four had been inoculated, some twice. Of these, five had fever, three not having been inoculated. Of thirty-five nurses, thirty-two had been inoculated twice, two not, as they had recently had the fever, one refused and she contracted the fever. He thought this showed the value of inoculation for a time—perhaps five or six months—and he thought that it rendered attacks less severe.

Dr Howard Tooth said his statistics were small, but favored inoculation. He thought the more severely the person reacted, the less the immunity; in Bloemfontein, officers who had had very severe reaction did not seem to be protected. He recognized three groups of people: (1) Those naturally immune, (2) Those rendered so by inoculation; (3) Those on whom immunity could not be conferred. Most persons belonged to the second group.

Dr. Rolleston remarked that inoculation did not absolutely protect, but statistics seem to show it rendered the disease less fatal. He believed there were different strains of typhoid bacillus, and infection with two or more was not proof against others. The serum, therefore, should be prepared from mixed strains, using as many sources as possible.

Surgeon-General Muir said far more statistics were required before deciding. He held, too, that typhoid was often conveyed from other sources than water.

Dr. Goodall also said too much stress had been laid on water supply, for many cases arose among those in attendance on the patients.

Dr. Washbourne, in his reply, said the test of inoculation in South Africa had been severe, but it is in persons frequently exposed to infection that it should be of most service. He did not think it should be used in England as the sources of infection are few; nor should it be lightly resorted to, for he had seen an officer laid up for three weeks with pyrexia after the injection. He did not consider immunity could be estimated by the bactericidal action of the blood.

You know that there are several endowed lectureships at the Royal College of Physicians. Three of these may be termed ancient, two are quite recent, dating in the eighties. The ancient ones are the Lumleian, Goulstonian, and Croonian. The Lumleian was founded in 1581 by Dr. Caldwell, who had been President of the college in 1570, and Lord Lumley, who was a considerable scholar. The Goulstonian was founded in 1632 by Dr. Theodore Goulston, the translator into Latin of several books of Aristotle and Galen. The Croonian, planned by Dr. Wm. Croune in 1684, was established by his widow in 1706. He was an early Fellow of the Royal Society, to which he contributed several papers.

The modern lectureships are the Bradshaw and the Milroy; the first in memory of Dr. Wm. Wood Bradshaw, D.C.L. Oxon., and a member of the college founded by a legacy bequeathed by his widow, who died in 1889; the other, founded in 1886 by the will of Dr. Garvin Milroy, who bequeathed £200 for the purpose and left suggestions for the guidance of future lecturers on the subject, which is State Medicine and Public Health.

Another lectureship is about to be endowed, which will bring the series up to six. This is in memory of Dr. Thomas Fitz-Patrick, whose widow devotes £2,000 to perpetuate his memory in this way, desiring the benefaction to be considered as coming from him and be called by his name, as in the case of Dr Croone, and the lectureship to be on the History of Medicine. The announcement of this new endowment was made very appropriately toward the close of the Harveian oration, delivered on October 18 at the college. The orator this year is Dr Norman Moore, and one of his duties is to commemorate "all the benefactors of the said college by name," according to the deed of gift which Harvey in his lifetime presented to the college. These benefactors have become too numerous to be each named every year, and Dr. Moore, having mentioned a number and their benefactions, was fain to conclude his enumeration, like an old charter, with the words *cum multis aliis*. He gave, however, some detail information about Dr. Fitz-Patrick: "He was a man imbued with learning, well read in Homer and Lucretius, and knowing Spanish, Italian, French, and German, as well as something of Hebrew, modern Greek, and Danish. His knowledge of English literature was extensive and his taste good. He had traveled as well as read, and having thus accumulated all the materials for conversation, he was a delightful companion. His intellectual attainments were the ornaments of solid virtues, and he deserves to be remembered with honor in this honorable place."

Dr Moore, before thus summing up the qualities of the man, had portrayed the surroundings of his childhood and boyhood at his birthplace in Virginia, a little town at the end of a long lake in Cavan. This is one of the poorer parts of Ireland, but the district is one of literary fame. The authors of the locality and their works, read by firelight far and near, were mentioned by Dr. Moore with the respect due to those who exercised great powers without hope of fame or reward, and who must have had an influence on young Fitz-Patrick.

Much the same method of commemorating the other benefactors was followed by Dr. Moore, picturing, as it were, the intellectual surroundings of each as well as their writings, libraries, and education. But the number to be named was too great to do more than, so to say, catalogue their qualities. If it were possible to confine each oration to one or two benefactors, there would be room for a picture of the period in which they lived or a sketch

of the intellectual society in which they moved. Here is a hint for future orators who fear the subject is exhausted and are not afraid to delve in the documents of history.

A new turn has been given to the election to the Medical Council. Dr. Glover retires. He has suffered from an affection of the eye and perhaps overwork. His advisers forbid him to take part in public meetings and recommend him to diminish his work. He therefore feels it better not again to be a candidate. He has served the office well and brought a strong intellect to bear upon the questions debated, and has held the confidence of the profession in his zeal and uprightness. Many thought he was not stiff-backed enough on the midwives question, and for this he would have been opposed. The election will probably be fought on that question, but we wait to see who will be the candidates to go to the polls.

H. Spencer Smith, Consulting Surgeon to St. Mary's Hospital, died on the 29th ult. at the ripe old age of eighty-nine—the last of the first 150 Fellows of the Royal College of Surgeons appointed on the origination of that grade in 1843. He served on the Council of the college from 1867 to 1875. He joined the staff of St. Mary's on its foundation in 1851 and became Dean of the school when that was established. He held the surgical lectureship for about seventeen years. Many other offices were filled by him—all with efficiency—in the course of his long career, *e. g.* Secretary and Vice-President of the Royal Medical and Chirurgical Society and Lecturer in the old Grosvenor Place School. He translated for the Sydenham Society "Schwann's Microscopic Researches." Some other works he also translated and he contributed to the journals and societies various papers. He well represented the "fine old English gentleman" with literary tastes. He was a bibliophile and in a position to gratify that penchant.

Dr. Alex. Hughes Bennett (only son of the eminent Edinburgh professor whose memorial laboratory was so lately opened) died on the 1st of November, aged fifty-three. He was physician to the Westminster Hospital from 1877 to 1893, when he resigned on account of ill-health. He was an original member of the Neurological Society and to its journal, *Brain*, he contributed numerous papers. Prior to this, he had written various articles on nervous diseases, and he was on the staff of one of the special hospitals for those diseases. But he was a victim to one of those very affections of an obscure nature and for many years a sufferer from frequent attacks of acute pain, similar to those observed in tabes, but he had no other indications of that disease. These attacks at length compelled him to abandon work.

DIFFICULTIES IN THE PRACTICE OF MIDWIFERY IN KOREA.

To the Editor of Medical Record.

Pyeng Yang, Korea, October 17, 1901.

Sir: In the July 20 number of the Medical Record, I read an article by Dr. Wm. Golden on "Clinical Notes and Comments." He certainly did operate under difficulties, but I wondered what the doctor would think if he was in this land and had to operate under difficulties fifty times worse than those he speaks of. It is hard enough sometimes at home, and I fully sympathize with Dr. Golden, but in these Eastern lands amid dense ignorance "denser than the very dense woods that surround their little cabin," the difficulties and discouragements one meets continually are almost enough to crush out the little hope remaining within you when called to attend your patient. In Korea, the surgeon has to speak in a strange language to a people sunk for centuries past in the grossest superstition and ignorance, who know nothing whatever of the foreign doctor's methods, and who regard all disease as either demoniacal possession or else due to demoniacal influence. As a rule, in obstetric cases, every available means at the disposal of the natives is first tried before the help of the foreigner is called in, as was the case with the one I here relate, and in Korea the mortality among women in labor is very great.

The patient was a girl, scarcely sixteen years of age, who began to be in labor Thursday evening, September 18. The pains at first were normal, but after a few hours increased in severity, and the patient and her relatives all thought that a boy baby, the joy of every Korean home, would soon be presented to the household, but in this they were disappointed. The husband, after inquiring of a neighbor as to the cause of the tardy labor, acting on his advice, killed a chicken, cut it open by an incision made from the neck to the anus, and then spread it out flat over the patient's sternum with the head pointing toward the uterus, the idea of this being that as the hen lays her eggs easily, by spreading it out over the abdomen the influence of the chicken would be transmitted to the patient, pains would be facilitated, and labor speedily brought to a close.

A single scale of a large fish was then placed on the plantar surface of one foot, the idea of this being that as the fresh scales are slippery, one placed upon the foot would act as a magnet and draw the fœtus toward it.

Both of these means failing to accomplish the desired result, the blind sorcerers were inquired of concerning the matter. This is the supreme court of the land when trouble of any kind comes to an individual. These worthies replied that if the obnoxious influence of the demon inside the uterus was driven out, all would be well, so the sorcerers were called to the house and for over two hours beat upon the drums and clattered with their cymbals, making as much noise as possible in the hope of driving the evil spirit away, but even this did not suffice, though the sorcerers had promised the husband that by the afternoon the child would be born.

Therefore inquiry was again made on Friday evening. The sorcerers divined the reason by casting lots and then replied that the evil spirit of the patient's mother, who had died several years before, had returned and entered the daughter, and if it could be driven out even yet all would be well. The influence of these demons upon the Korean mind is tremendous. "They occupy every quarter of heaven and every foot of earth. They lie in wait for him along the wayside, in the trees, on the rocks, in the mountains, valleys, and streams. They are all about him, dance in front of him, follow behind him, fly over his head, and cry out against him from the earth. He has no refuge from them even in his own house, for they are plastered into or pinned on the walls, or tied to the beams. Their fetiches confront him in the entrance, and there is a whole row of them back of the house." But I am departing somewhat from my history.

The second time the drums and cymbals were called to the house and greater noise than ever kept up for about three hours, petitions were offered to the spirit asking for safe deliverance of the child, after which food was prepared and placed before him in order to strengthen him for his return journey to the far country, from which he had come. But still there was no end to the labor, and Saturday morning dawned bringing to the whole household, and even to the whole neighborhood, a great deal of anxious concern for the safety of both mother and the coming child.

Toward evening the husband takes an ox saddle used for carrying merchandise, and fastening it upon his back ascends the roof and then walks on all fours backward and forward, ending up with bellowing like an ox, repeating this three times. This belief is that for the time being husband and wife become cows, and as this animal usually has easy labor, by imitating it, safe and rapid delivery would soon result. But alas! even this failed to accomplish the desired end, labor was no more advanced than before, the patient was becoming exhausted, and unless something desperate was done all hope would soon be past. The sorcerers had previously told the husband not to ask help of the foreign doctor, as it would not avail in the least, but finally, as a last resort, Dr. Lillian Harris was called in to see the case, and to try to drive out the powerful demon and "give life" to the woman. The writer was invited to assist the doctor, and together we went to the home.

It was half past nine when we reached the patient's home, which consisted of two small rooms, each seven feet nine inches square, and barely high enough to enable one to stand upright. The house was nothing more than a hovel with a straw roof, mud walls, and floor, the warming of the rooms being done from a fire kindled in the kitchen and running through flues underneath. The natives use no chairs or bedsteads, but sit, eat, and sleep on the warm floor. The only light comes from one small door covered with stout white native paper, and ventilation is furnished through two or three holes the size of a dime punctured through the paper.

We found the interior of the house filthy, the patient lying on a very dirty mud floor covered with a cheap straw matting, and clothed with garments that once were white, but had not seen the wash tub for at least three months, and I doubt very much if our patient's body had seen the bathtub for twice that length of time. Fortunately, we brought a good lantern that gave more light than a dozen such as our friends possessed. Our surgical staff consisted of Dr. Harris, myself, the husband of the girl in labor, who was about as stupid and dense a piece of humanity as one could possibly find, and the mother-in-law, who was a trifle higher in intellectuality. With this finely equipped staff of doctors and trained(?) nurses, chloroform was administered by the writer, and Dr. Harris made an examination after having previously catheterized the patient with much difficulty. The cervix

was completely dilated, and a loop of the membranes containing a little water was protruding from the vaginal outlet, which was thought by the relatives to be part of the fœtus, and who told Dr. Harris "the baby is coming." The occiput was slightly below and to the left of the promontory, the bregma was easily accessible, and the upper edge of the frontal bone was lodged on the symphysis. Several attempts were made to flex the somewhat extended head, but were unsuccessful. The occiput was very tightly impacted in the pelvic brim. To delay further would be dangerous; in fact, delay had already become so to the mother and child, for the pulse was rapidly increasing and the woman becoming exhausted, so forceps were applied and the fœtus extracted by a single application lasting over two hours. Manual pressure was made over the abdomen and the placenta quickly expelled. Ergot was given, one drachm, and repeated in two hours on account of rather free flowing, and then four sutures were taken in the soft parts which were torn down to the sphincter ani. The child was dead when delivered, having been so for an hour. The left side of the cervix was badly torn, but was not repaired at the time, as the condition of the patient would not permit of any further interference.

Before leaving the house, Dr. Harris made the woman as comfortable as possible by cleansing her and placing her upon clean, dry matting, to the evident concern of the household, who thought it rather a waste of precious time.

For the first few days after labor, the temperature ranged from 100° to 103°, and the pulse as high as 125, due doubtless to sepsis, but no serious results followed, and otherwise the patient made an uneventful recovery.

There is nothing special in this case except to show the difficulties under which we, in Eastern lands, amidst dense ignorance and superstition, have to labor. The wonder to me is that many more women do not succumb than is generally the case. Even though the doctor tries his best to be aseptic in all details so far as he is concerned, his efforts are counteracted by the unclean habits of the patient and her friends. Of course in this instance, as in every other, if we had been called as soon as labor commenced, the girl would have been removed to the hospital, but when we saw her it was impossible; whatever was done must be done at once, or our patient would have speedily passed beyond the reach of any earthly help.

E. Douglas Follwell, M.D.

LETTER FROM CONSTANTINOPLE.

(From our Special Correspondent.)

A TRIVIAL CAUSE FOR A MEDICAL QUARREL—QUARANTINE AGAINST THE PLAGUE IN CONSTANTINOPLE—THE FUNCTIONS OF THE INTERNATIONAL HEALTH BOARD—PERSONAL NEWS.

Constantinople, October 15, 1901.

With the exception of quarantine, there has been nothing worth recording in the medical world of Constantinople. The system of "Villegiatera" prevails, and in summer doctors and patients go to the Bosporus villages on the islands of the Marmora, from which they have just returned.

The medical society has resumed its labors, and at the two first meetings of the season engaged in a trivial dispute—scarcely a discussion—on the treatment of hemeralopia by liver. So much cross feeling arose that on the motion of Prof. Dr. Remlinger the resolution was adopted that the word hemeralopia should not be mentioned in the society for six months! Anything more puerile in medicine is scarcely conceivable. Dr. Nicolle, the French bacteriologist, a distinguished pupil of Pasteur, has quitted the Turkish service. Mr. Beach, the Indian expert on plague, continues to assist the Municipal Sanitary Council, presided over by Redvan Pacha. This municipal body, as foretold in August last, has built its own lazarette at Beicos just a little too late to meet the conditions likely at the time to require such accommodation. It may, however, be useful in future, which is a distinct gain.

The proceedings of quarantine have been as erratic as the plague itself. On August 17, the constitutional period of ten days was reduced in Bulgaria to forty-eight hours, in Greece to five days. On August 20, quarantine was suppressed, but on the 21st, on the report of a suspected case of plague, it was renewed in full force, and so on intermittently the see-saw process was repeated up to September 10, when another alleged case was reported at Kauskaunjauk, on the Asiatic side of the Bosporus. A ridiculous incident occurred: a man presented himself at the Greek Hospital of "Yedi Kaulè" (seven towers) for treatment. He was considered "suspect," and consigned to the barrack in the hospital grounds for further observation. During the night he escaped and walked or ran from "Yedi Kaulè" to Baluk Bazaar (fish market) in Stambul, a stiff walk for one in health. He was pursued, and found enjoying his pipe and coffee. He and others with whom he had been in contact were interned. It was explained that he had wandered in the delirium of plague.

October 19, when plague was supposed to have spent itself and active officials were about to receive the reward of their labors, four more cases were announced as having occurred in a Greek family in Galata, of which one died. The patients and the other occupants of the premises, stated to be thirteen in number, were removed to the newly erected lazaret at Beicos. On October 21 a reimposition of quarantine was made by Greece, Bulgaria, and Roumania. "Travelers from Constantinople cannot pass the Bulgarian frontier at Hebibtchéno until after having undergone a quarantine of five days, and after disinfection by steam of their luggage and all other effects. The provisions of these voyagers will be destroyed by fire. The express train will pass in transit through Bulgaria and be accompanied by a lazaret doctor from Hebibtchéno to the Servian frontier, it being strictly forbidden to travelers and employees of these trains to descend at the stations, and equally forbidden to be in contact with any persons at the stations. Merchandise from Constantinople is interdicted. Postal correspondence from Turkey cannot enter except by Hebibtchéno and that for the interior of Bulgaria will be retained at the lazaret there for disinfection.

By reason of this plague scare, sanitary and hygienic rules and regulations have become somewhat mixed. The following municipal dispositions have been decreed for the sanitary inspection of public establishments, and medical visit of cooks, waiters, and all other employees of restaurants, etc.: 1. As the municipal doctors cannot visit and attend every one of these classes and determine if they be affected with contagious diseases, practitioners are bound to notify the cases they attend. 2. All cooks, lemonade-dealers, etc., who shall be declared suffering from a contagious disease, should cease their work and go to a hospital, but if they can be attended at their home this privilege will be accorded to them. 3. No person should engage a cook, domestic, etc., without a medical certificate declaring that he is healthy. 4. No person of the category mentioned shall contract marriage without a medical certificate. 5. Doctors who deliver false certificates will be dismissed if they are officials, or fined if they do not belong to a service. Cooks, lemonade-dealers, waiters, etc., who are not visited every six months for obtaining a certificate of health as provided will be liable to a fine. 6. For the first medical examination they will be charged fifteen piastres for the certificate delivered, and five piastres for a photograph of the person visited. This latter shall be pasted upon the certificate of health. The medical visit shall be passed twice a year; five piastres shall be charged per visit." A truly wonderful application of the principles of sanitary science, highly imitative, though not to be imitated!

The worried shipping interests are very impatient at the oddities of the past nine months of quarantine as applied against Turkey by Greece, the Balkan States, and Egypt, and also by Turkey against Egypt. Their representatives ask what really are the attributes and functions of the International Health Board, and how far this sanitary body is in accord with the municipal health organizations, forgetting, or not knowing, that these organizations are independent of each other. Is it, they ask, a consultative body for advising the various nationalities on the propriety of imposing quarantine under certain conditions, or is it a number of European delegates appointed merely for the purpose of reporting isolated cases of cholera or plague, and leave their respective governments to impose quarantine without reference to the means and authority of the board to isolate such cases, and so obviate the necessity of quarantine, or at least to modify it? The prevailing opinion is that, so far as Turkey, Greece, Bulgaria, Servia, and Roumania are concerned, the time has come for a fresh International Health Congress to bring matters more into accord with the present-day knowledge of sanitary science.

The International Health Board, so called, is a somewhat ancient institution, dating from the reforming days of Sultan Abd-ul-Medjid. Its functions then were clearly defined, it advised on all question of public health, it regulated bills of health, *patents de santé*, in pre-telegraphic days when bills of health served a purpose—stamped as they were with a consular visé. Bills of health serve only fiscal purposes nowadays. Thus, a vessel may leave a port furnished with a clean bill of health; a few days after departure, a case of cholera or plague may declare itself in

that port. Information of this is telegraphed abroad long ere the vessel reaches her destination. The clean bill of health is not accepted, and the vessel has to undergo quarantine in detail, although free from infection, as stated in the bill, unless the voyage be long enough to enable her to "purge" quarantine at sea. This frequently occurs in the trade between India and the Red Sea. On this one point there is room for improvement, to say little of the modifications or suppression of land quarantine at the different frontiers—almost universally condemned as futile—and especially with regard to the many articles of commerce now considered incapable of carrying infection.

For many months past, plague, or whatever the malady may be, has been cropping up at long and irregular intervals in Constantinople and its suburbs, each case being followed by full quarantine. The consequences are disastrous to commerce; the personal sacrifice and inconvenience to travelers are so great that one might prefer the risk of plague to the terrors of quarantine.

On October 24, another suspected case of plague was reported as having occurred at Bechiktash, a suburb on the European side of the Bosporus. It may be that plague is in our midst, and that the dread of isolation and removal of whole households to a lazaret prevent the cases being notified, otherwise it is difficult to explain the position.

From Egypt, Naples, and Samsoun, where the disease prevails, the public journals give full information of its course and progress, but in deference to Imperial solicitude for the public welfare, nothing of what occurs in Constantinople is vouchsafed. The word plague is officially abolished.

Dr. Constantanides, surgeon to the Municipal Hospital, died on October 22 from scarlatina after a short illness of three days. Dr. Clemow, physician to the British Embassy and British Health Delegate, has returned from sick-leave.

Dr. Remlinger, Director of the Antirabic Institute, has been appointed by Imperial iradè chief of the Imperial Bacteriological Institute, replacing Professor Nicolle. Dr. Reminger will continue also to hold his former post

THE REORGANIZATION OF THE PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

To the Editor of the Medical Record:

Sir: The time has come when the public has a right to know exactly what is meant by the much-talked-of reorganization of the Pathological Institute. There seems to be no certainty that the State Commission of Lunacy is dealing frankly with the situation. We hear of avowals to continue its work, but when we are shown the machinery for this work there appears to be no intention of continuing anything more than the name of the institute.

Reviewing the recent history of this unfortunate institution, we find that the State Commission, which was expected to protect the work, resolved to destroy it, without trial or hearing. Following this were the cutting off of its maintenance and the dispossession of its domicile. In the midst of its work, the apparatus and instruments were seized and thrown into the asylum vaults at Ward's Island, where neither quarters nor means for the work was possible, and a large amount of scientific research extending over years was ruthlessly destroyed. The commission, however, was forced by the situation in the Legislature of the State to promise to continue the work and even to retain the director. But no sooner did the commission obtain the needed appropriations than it proceeded to demand the resignation of the director and the whole staff of men constituting the Pathological Institute, and without making any charges of incompetency or unfitness to do the work. The specious plea was advanced that the prospective director must have his hands free in the reorganization of the institute, when there is evidence to believe that it is the intention to organize a very different kind of work under the old name. At any rate, there is no frankness with the public, that has supported the work of pathological investigations, while a scientific institution is complete destroyed. It was hoped that the new President of the commission would support, as he promised, a work so important to the treatment of insanity and the study of abnormal psychology. The time is ripe for the proper study of pathology in both physiology and psychology in this country, as it has not been done in the past, and it is work that can be done only by those who have made themselves familiar with it. A man who has never done a day's work in psycho-pathology of any sort is not the man to act as advisor in so important a subject, and it appears that the "reorganization" will depend, somewhat at least, upon the judgment of that kind of an "authority." If the State Lunacy Commission will not see to it that the institution is preserved in all its integrity, the public will have to see that private schemes and ambitions are not gratified at the expense of science. I am not speaking here in behalf of any particular person or set of persons, but only of a work which needs to be done and done by men who are qualified by experience to do it. More particularly, I am speaking in behalf of some continuity in scientific work, and the study of problems that the physician and the alienist can appreciate as no one else can. It is time to take the whole subject out of politics and private ambitions, and it is hoped that the public interested in it will see that this is effected. The State Commission must either be forced to do its duty or frankly and openly to indicate its policy without subterfuge and evasion and the shifting of responsibilities

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 21, 1901.

Lesions of the Bladder During Abdominal and Vaginal Hysterectomy.—Charles Greene Cumston says that out of some 300 abdominal sections for gynecological affections, he has wounded the bladder but once, and once only out of 74 cases of vaginal hysterectomy. To close bladder wounds, he uses two layers of sutures, the first of which includes the mucous membrane alone; for this fine catgut should be used. The second and superficial layer includes the muscle. If the bladder is deeply seated, and if the abdominal walls are very thick, the mucous membrane may first be united by interrupted sutures of fine catgut, but if the wound in the bladder is easily accessible, a running suture is to be preferred. As to the superficial suture, it should always be done with a running Lembert's suture. In some cases, especially if the wound in the bladder is a long one, these two layers of sutures may be reinforced by a third layer of Lembert's suture.

Some Deductions Concerning Milk Modification.—R. C. Macdonald says that the main efforts of milk modifiers have been directed to the reduction of the so-called casein, and to the replacement of the fat. Practically no attention is given to two very important points of difference in human and cow's milk. Casein consists of caseinogen and lactalbumin. In human milk these two substances exist in equal proportions, while in cow's milk there is but one part of lactalbumin to six parts of caseinogen. Furthermore, in cow's milk, phosphorus exists mainly in the form of inorganic compounds; in human milk it exists in organic combinations. The former are practically non-assimilable; the latter are readily taken up by the human system. The author suggests that both these deficiencies can be somewhat overcome by a judicious use of the whole egg. Egg albumin approximates quite closely to lactalbumin, and in the egg yolk we have a veritable storehouse of organic phosphorus compounds. With a proper percentage of cereal to break up the curd, and judiciously regulated proportions of whole egg added to cow's milk, as now modified, the ideal of "mothers' milk" would be reasonably in sight.

Suggestions for the Improvement of Training-Schools for Nurses.—Richard C. Cabot hopes that in the course of time, nursing may be made a liberal profession. To that end, there should be certain improvements in the methods of educating nurses. In the first place, nurses should pay for their training, and be taught by paid instructors. This would tend to bring into the profession a better-educated class of women, and would put the students in a position to demand, instead of humbly requesting, a thorough course of instruction. Nurses should be taught by nurses, medicine by physicians. Nurses should be prepared for private nursing by practice in families outside a hospital, and by the teaching of nurses in active practice. The nurses' training should not be exclusively technical, but should include some liberal studies, such as sociology, history, and literature. She needs to study subjects which tend to give a deeper and truer sympathy with human nature, and also to prevent her from getting warped and depressed by the weight of concentrated sorrow and suffering which her life forces upon her notice. The educated nurse has resources to turn to when her work is done, and can carry with her into her work a consciousness of other and more normal sides of life, which will give her balance and enthusiasm in the thick of her difficulties.

Journal of the American Medical Association, Nov. 23, 1901.

Treatment of Ringworm of the Scalp in Institutions.—H. W. Stelwagon advises the clipping of the hair or in obstinate cases the shaving of the scalp every few days,

The latter is to be washed with medicated green soap. Various formulæ are given for local applications which the author has found of service. He attaches greatest value to chrysarobin, which, however, must be of the best quality. It must be employed with great care when the patient is under three years of age. A saturated solution in chloroform is the preferable combination. In very young patients a naphthol salve or tincture-of-iodine paintings will effect a cure.

Two Different Ways in Which Yellow Fever May Be Transmitted by the Culex Mosquito (Stegomyia Tæniata).—C. J. Finlay says that there are two different ways by which the specific germs of yellow fever may be conveyed from the sick to the healthy. One way consists in allowing the yellow-fever mosquitos to become infected in such a manner that after the lapse of a certain number of days the salivary and venom glands of the insect appear to become the seat of a local, chronic, life-long infection which is attended with a constant reproduction of yellow-fever germs so that the contaminated mosquito will thereafter inoculate some of those germs with every bite. The other way consists in injecting the germs contained in the blood of a yellow-fever patient directly under the skin of a non-immune.

The Non-Surgical Treatment of Heterophoria.—Dr. G. M. Gould lays down the factors of proper treatment as follows: (1) The absolutely accurate estimation of the refractive errors by cycloplegia and the subjective method and the prescription of spectacles and their adjustment according to the hundred modifying conditions of the individual case. (2) When the heterophoria is three degrees or over, a temporary but partial neutralization by prisms may be necessary to tide over the period required by nature to reinforce a normal balance of innervation. (3) Supplementary ocular gymnastics, mere excursions of the eyeballs upward and downward, etc., aid in bringing about balance. (4) Instruction in ocular hygiene is frequently helpful. The book habitually placed too far below the horizontal plane may be productive of much eye strain. High arm-chairs and other similar devices would vastly lessen the sufferings of many people.

The Psychoses of Chorea.—H. N. Moyer presents the following conclusions: (1) A well-marked alteration of the character and mentality can be noted in the majority of cases of chorea, usually preceding by some weeks the onset of the choreic movements. (2) Distinct hallucinatory phenomena are present in a considerable number of cases, which are not, however, of sufficient severity to merit being classed as a distinct psychosis. (3) The mental disturbance in chorea usually comes on after choreic movements, but it may precede them. (4) The type is usually maniacal, though it may occasionally be melancholic or present the character of an acute delirium. (5) Mental disturbances are commoner in older children; they are rarely observed before the twelfth year. (6) Choreas which are accompanied by mental disturbance later in life are almost always accompanied by organic changes in the central nervous system. (7) The prognosis is favorable when the mental disease complicates the simple, acute chorea of Sydenham. Insanity associated with chorea in middle and advanced life is almost invariably associated with organic disease of the central nervous system.

New York Medical Journal, November 23, 1901.

Leucoplakia.—J. V. Shoemaker gives the clinical histories of two cases and a general description of the disease. It calls for a differential diagnosis from syphilis, tuberculosis, epithelioma, chronic glossitis, and opaline patches. Shoemaker advises a cautious local therapy and the avoidance of escharotic measures.

Cyst of the Vermiform Appendix.—W. C. Wood reports a case of a woman of twenty-five years, supposed to be suffering from an attack of acute appendicitis. She gave no history of ever having had a similar attack, but just twenty-four hours previously had been taken with severe pain in the stomach, nausea, and vomiting; the pain soon shifted to the region of McBurney's point, and there was a slight rise of temperature. When first seen she was acutely tender over the appendix, there was marked rigidity of the right rectus muscle, and the abdomen was somewhat distended, especially on the right side. The pain was severe, but not constant. The bowels were moderately constipated. On opening the abdomen by the usual incision a transparent tumor, dark-colored and filled with fluid, presented in the opening. At first the author thought it might be a strangulated intestine, but on drawing it out of the wound it was found to be attached to the head of the colon, and was, in fact, a cyst of the appendix. The tumor was removed by clamping its base and cutting close to the bowel, which was secured by inverting the stump into the bowel and overcasting with several interrupted sutures. The cyst contained six ounces of fluid of a light straw color similar to that found in a hydrocele. The patient made a prompt and uneventful recovery.

The Advantages of a Trace of Albumin and a Few Tube Casts in the Urine of Certain Men Above Fifty Years of Age.—W. Osler says that it is more important to base a judgment on the general condition of the patient than on the result of uranalysis. Some men when applying for life insurance are rejected because a little albumin and a few casts are found in the urine. They are generally men who have been high livers, hard mental workers, and without proper exercise. The appearance of the danger signal, as above noted, leads them to reform their mode of living and they begin to conduct themselves rationally. In other words, Osler wishes to call special attention to the fact that in men in the fifth and sixth decades albuminuria is by no means infrequent and not always serious. It is probably the expression of presenile changes in the kidneys, the result of arterial degeneration, and is often a renal inadequacy, to use Clarke's term, not of vital importance. Neither the presence of albumin nor the number and variety of the casts have the same value in estimating the character of the disease, and the prognosis, as other factors. The points on which one should lay special stress as indicative of serious disease are: 1. Persistent low specific gravity of the urine, 1.008 to 1.012. 2. The state of the heart and arteries. Marked sclerosis of the peripheral arteries, with the apex beat of the heart an inch or two outside the nipple line, and a ringing, highly accentuated aortic second sound. 3. The presence of albuminuric retinitis. A strong exhortation is made by the writer that every man should after fifty gradually decrease the amount of food taken.

Philadelphia Medical Journal, November 23, 1901.

The Supraorbital Reflex in Facial Paralysis.—Joseph Sauer speaks of the demonstration of the supraorbital reflex by D. J. McCarthy. He then reports three cases which appear to prove that McCarthy's reflex is a true sensorimotor reflex, and that the irritation of the supraorbital nerve may, under certain circumstances, produce contraction of the muscles of the opposite side. Also that in certain cases the reflex manifestation may extend to the other muscles which are removed to a considerable distance from the supraorbital nerve. In two of the cases there was loss of ability to move the platysma.

Technique of Vaccination.—Frederick A. Packard declares that the object of vaccination is to cause the virus to become disseminated through the body and produce general immunity from variola. This virus should be free from contamination. The writer advocates the use of the hermetically sealed tube containing glycerinized lymph. The physician should have at hand soap and water, alcohol, clean vaccine, and some form of protection to apply after the operation. The vaccine points are kept in the refrigerator between vaccinations. Preceding the operation, the hands of the operator are scrubbed with soap and water and then wet with alcohol or corrosive-sublimate solution. The skin of the patient should be sterilized. This involves scrubbing with alcohol, as this promptly evaporates and does not destroy the virus. As an instrument, the writer prefers a special scarificator. As to the point chosen to scarify, the area near to the deltoid insertion is preferable. If the leg is to be vaccinated, then the point just below the head of the fibula is chosen. Scar tissue must be avoided. The ideal result of the scarification is to obtain a little pinkish or rosy moisture, not to draw blood. On this the vaccine is deposited, and the surface is finally again scarified enough to rub in the vaccine and yet not to cause the outflow of blood. The celluloid shield is applied, but is removed as soon as a specific local lesion is produced. The arm is then dressed with boracic-acid ointment.

Prophylaxis of Smallpox in Cities.—Richard A. Cleemann states that the duration of immunity from smallpox secured to the individual by a single vaccination is estimated on good authority to be from eight to twelve years. There should be as general a vaccination as possible by a corps of vaccinators, who should be educated physicians under the order of the health authorities. Discretion should be observed with regard to weak children and sick persons. The operation should be avoided generally in hot weather upon infants less than two years old on account of the possible complication of cholera infantum. A child that cannot furnish a certificate of successful vaccination should be prohibited from attending any school or institution where children are received. Vaccination should be made a prerequisite to entrance into the civil service, the army, the navy, and

the militia. No immigrant should be allowed to land on our shores unless thus protected from smallpox. When the disease actually appears in a community, the most thorough precautions should be taken. The case should be reported immediately to the health authorities, who at once send a medical inspector with a vaccinator to verify the diagnosis, and in this event all unprotected persons in the environment of the patient are vaccinated. The origin of the disease should be traced and reported. The patient with the rest of his household should be removed to a hospital devoted to the care of smallpox cases, where they are to be detained until the vaccinations prove successful or until they remain well for two weeks. The room and all its contents should be thoroughly disinfected. If the patient is living in his own house, and insists on remaining, guards must be placed before the door to insure that no one but the physician goes in or out. The utmost precautions must be observed to prevent any possible spread of the disease. Should the patient die, the body is to be wrapped in a sheet saturated with corrosive-chloride solution, and preferably cremated. The remains may be encased in a hermetically sealed metallic coffin and carried, without a public funeral, to the grave.

Some Experiences with Blood Examinations.—John B. Deaver and Edward Kemp Moore present this paper. They state that undoubtedly examinations of the blood for the hæmatozoa malariæ are of the greatest value, and when these organisms are found they are absolutely diagnostic of the disease, but it has been the authors' experience that the more irregular and atypical the case of malaria, the harder the organisms are to find. They also conclude that a positive Widal is rarely of much value to the surgeon, however valuable it may be to the medical man. A negative Widal reaction, especially after an illness of two or three weeks, seems more often of service. To demonstrate sugar in the blood is more interesting than valuable. Justi's hæmoglobin test for the diagnosis of syphilis has proved very satisfactory in the writers' cases, and in a doubtful case is worth a trial. The erythrocyte count gives the surgeon an index as to the powers of resistance of a patient as well as a guide to the severity of the infection. A chlorotic condition of the blood is often valuable in explaining the cause of amenorrhœa and leucorrhœa in young girls, as well as in other conditions. The writers consider the subject of leucocytosis the most valuable and the most disappointing part of the examination of the blood. They relate the case of a young man who was admitted to the hospital with all the symptoms of a severe attack of appendicitis, the leucocytes on the day of admission numbering 20,000. Operation was refused by the patient. He was treated medically with improvement in all symptoms, the leucocytes gradually fell from day to day, and after six days they numbered 7,500. At this time, permission for operation was granted and a large abscess was found in the pelvis, containing at least 500 c.c. of pus. At the time of operation the temperature was normal, the bowels were moving feebly, pain was absent, and the stomach was retentive. The only indications of the abscess were tenderness and rigidity of the right rectus and a mass discernible upon rectal examination. In this case the blood examination proved itself entirely unreliable. The writers, although having no desire to belittle the real value of blood examinations, object to the unfounded claims that have been made which experience does not bear out.

The Lancet, November 16, 1901.

Notes of a Severe and Long-standing Case of Lupus Treated by the Application of the X-Rays.—G. H. Rodman's patient was a woman of thirty-eight years, suffering twenty years from lupus said to have followed an operation for the removal of the malar bone. X-ray treatment was applied for over three months, there being some fifty exposures made. Complete healing resulted.

A Case of Lupus Vulgaris Treated by Exposure to X-Rays.—T. C. Squance reports the case of a girl of seventeen years with lupus of the nose, lip, cheeks, lower eyelids, forehead, and angle of the jaw. X-ray exposure ten minutes was given three times a week. After the first exposure there was decided flushing, accompanied by some pain, tingling, and a sensation of heat, which continued more or less markedly after each sitting, the skin assuming a reddish-brown appearance with yellowish crusts. Later daily exposures were made until the reaction became so marked that the treatment had to be intermitted. Results of treatment were most satisfactory, the patient being practically cured. Squance thinks that the action of the rays in these cases is probably a dual one. On the one hand, there may be excessive stimulation of the bacilli causing "over-population," and consequent dearth of food, and on the other, there may be produced an inflammatory reaction in the healthy tissues on the margin of and below the diseased portions, causing them to put on an increased resistance.

Curious Symptoms After the Extraction of a Tooth.—W. C. Pudham reports the case of a man aged thirty years who suffered from a fractured tooth. The fracture had been done a week previously, and in the interval the man had suffered extreme pain. The roots of the first molar on the left side were removed without difficulty, the patient, however, immediately subsequently to the operation, complaining of great pain. This was almost immediately relieved by the application of hot water to the gums, and at this point the patient appeared to be quite well. Within five minutes of the extraction, he complained of severe "pins and needles" in the legs and arms, became rigid and quite cold, with a bad color, hurried respirations, dilated pupils, strong contractions of the muscles of the arm and forearm, flexure of the fingers, and considerable adduction of the thumbs. The teeth were clenched, but the patient was able to answer questions with some difficulty, and he remained conscious during the whole attack, which lasted for about half an hour. The hands and arms were well chafed and doses of sal volatile were administered. The patient was eager to be allowed to sit up, at least partially. The symptoms yielded to continued efforts to restore warmth, and the man recovered slowly till he was able to warm himself by swinging his arms about. He eventually left the hospital apparently little the worse for the attack.

Berliner klinische Wochenschrift, November 4, 1901.

Treatment with Frey's Hot-Air Douche.—B. Belzer warmly commends this method and gives a series of histories of cases that were very greatly benefited by its application. The apparatus has none of the disadvantages of the forms of hot-air treatment in vogue, which require for their administration separate rooms, the presence of skilled attendants, uncomfortable postures, and considerable reactive power on the part of the patient. It can be used in any consulting room provided with an electric lighting current and can be instantly got ready for use, while manipulation of the rheostats permits the modification to any degree of the temperature and force of the blast of heated air. Burns are impossible and any part of the body can be subjected to the treatment, which is advantageously carried out together with massage. The intense local hyperæmia induces more active cellular metabolism, facilitates the removal of waste products, and aids in the absorption of objectionable deposits of all kinds. The main field of usefulness is therefore in gouty, rheumatic, and neuralgic states, though the author enthusiastically prophesies a great future for it in many other directions.

Colpocœliotomia Anterior-lateralis; a New Vaginal Operative Route Into the Abdomen.—A. Dührssen says that his method of vaginal celiotomy has been criticised on the score of the technical difficulties sometimes encountered, and he has therefore devised a modification which he thinks will obviate these objections. This simplified method consists in a combination of vaginal celiotomy with the complete division of one broad ligament. The advantages of the method are as follows: If the operation is begun with the division of the ligamentum cardinale without opening the anterior and posterior *culs-de-sac*, parametric abscesses or purulent accumulations in the tubes and ovaries can be opened extraperitoneally and without sacrificing the adnexa. If removal of the adnexa is intended from the first, access to the abdominal cavity is in this way made much more free, and since all of the uterine attachments except those with the undivided ligament are cut through, the whole organ may be drawn out through the vulva, leaving a clear field behind. The extraperitoneal fixation of an infected tubal stump and drainage of the entire pelvis are easily effected. This form of operation makes control of hemorrhage possible under all conditions and frequently makes the otherwise sometimes unavoidable total extirpation of the uterus unnecessary. In cases of large laterally situated ovarian abscesses or pus tubes that may be treated by simple incision and drainage, the first stage of the operation, *i. e.* the division of the ligamentum cardinale alone, is sufficient. Complete division of the whole broad ligament is indicated in difficult cases of adherent uterus, infiltrated and inflammatory adnexa stumps that require extraperitoneal fixation, peritonitis, and conditions requiring pelvic drainage, in cases of hemorrhage, and of rupture of the uterus.

Munchener medicinische Wochenschrift, November 5, 1901.

A Case of Rheumatic Disease of the Temporo-Maxillary Articulation.—Hamm describes a case in which the patient, a man of forty-five years, could not press the jaws together without severe pain. A small blood cyst of the external auditory canal was found and punctured, but

with at relief to the painful mastication. After a week of useless therapy, the condition quickly subsided under the administration of sodium salicylate, and the author says that in similar cases of obscure pain in this region, one should always keep this unusual but possible lesion in mind.

Occupation-Neuritis of the Brachial Plexus.—L. Hoeflmayr describes a somewhat unusual affection of the nerves supplying the deltoid and latissimus dorsi. The patients were carpenters, tanners, and a watchmaker and had all been for some time treated unavailingly for rheumatism. In each patient, the trouble had developed slowly and was independent of trauma or exposure. None of the patients gave a history of previous rheumatism, syphilis, of alcoholism, or any chronic intoxication. The pain was always situated about the shoulder joint and was so great as to prevent all motions involving the muscles named. The author believes that it was a neuritis induced by the occupations of the patients, which were of a nature to call these muscles into constant play. The prognosis of the affection is good, though eight to nine weeks elapsed in these cases before the cure was complete. The treatment comprised rest, local heat, and galvanism to the nerves with, and later on, faradism to the muscles.

Two Cases of Foreign Body in the Nasal Sinuses.—Lohnberg has seen two instances of foreign bodies in the accessory cavities of the nose, one in the ethmoidal cells and the other in the frontal sinus. The first case was in a man of forty years who sought relief for a large mass of polyps filling the whole of one nasal cavity. After their removal, a hard body was felt in the vault of the naris and on extraction was found to be a fragment of iron 2 mm. thick and more than 2 square cm. in size. The patient then recalled that twenty years previously he had lost the corresponding eye through the explosion of a gun while hunting. The foreign body had evidently penetrated the os planum of the ethmoid bone and then come to rest in the ethmoidal cells. The second man received a blow on the forehead with a wrench which broke in the frontal sinus. Long-continued suppuration with discharge into the nose led to operation, which revealed the presence of a good-sized piece of felt that had been torn from the patient's hat and carried into the wound by the blow.

A Case of Late Meningitis After Cranial Trauma.—Kokke Fujisawa says that even after a cranial injury has apparently cleared up without after-effects, if a fissure be left behind communicating with the air through nose, mouth, ear, eye, etc., a meningitic process may develop after years through infection by this channel. His patient was a girl of ten years who over twelve months previously had fallen and suffered a depressed fracture of the left side of the forehead. After an illness of two months, she had completely recovered and showed no bad effects from the accident. At the time of examination, there was evidence of acute meningitis, and twenty-four hours later she died. The autopsy showed acute leptomeningitis with a focus of yellow softening at the base of the left frontal lobe. A small dark fissure was found in the frontal bone connecting with the lamina cribrosa. The author believes that the softening occurred at the time of the injury, a year previously, and lay dormant till infection took place through the crack leading into the nose.

Deutsche medicinische Wochenschrift, November 7, 1901.

An Unusual Type of Cirrhosis of the Liver.—L. Jones reports a case of this lesion in which both syphilis and alcoholism were absent from the past history. Eleven years previously the patient had suffered from some gastric affection which he described as having been of short duration and from which he experienced no further trouble. Notwithstanding the apparently benign nature of this trouble, the autopsy, which was performed two months after the onset of the hepatic symptoms, revealed extensive changes in the gastric mucosa. There was evidence of gastritis and even to the naked eye numerous small cicatrized ulcerations were visible, while in these spots the normal glandular structure was entirely replaced by connective tissue. The liver was greatly altered, and large yellow patches were found imbedded in a tissue of a grayish-red color which did not resemble liver structure. The author believes that a more direct connection is possible between gastric disease and cirrhosis than is generally believed, and cites some experiments on animals which appear to support this view.

Studies on the Epidemic Dysentery of Japan with Especial Relation to the Bacillus Dysenteriæ. K. Shiga says that this organism is found in all cases of the disease, but never occurs in healthy individuals or those suffering from other maladies. It is most abundant in the deeper layer of the intestine, whence it may be obtained in pure culture, but in old ulcerative foci and on the surface it occurs sparsely and is overgrown by other colon bacilli. The organism, or its toxins, is capable of producing hemorrhagic extravasations, and in animals causes subcutaneous extravasation and bleeding into mucous and serous membranes, such as are often observed in severe cases of dysentery. The bacillus of dysentery produces agglutination with the blood of dysenteric patients, but not with that of any others or of the healthy. This agglutinating power undergoes variations and is greatest during convalescence, after which time it again gradually sinks. Injected into the healthy, the dead bacilli produce violent local inflammatory reactions, but in dysenterics are more easily destroyed and absorbed. An immune serum may be prepared having preventive and therapeutic properties in relation to the disease. In distinguishing amœbic colitis from the bacillary type of the disease, the following points are of value: Amœbic dysentery is chronic and is not accompanied by the presence of the specific bacillus. The so-called toxic symptoms are not observed in amœbic colitis, viz., fever, general prostration, headache, loss of appetite, rapid emaciation, hemorrhagic and nervous manifestations, etc. In the amœbic form, liver abcess is a frequent complication, but this has not been observed in the epidemic type. In amœbic dysentery, the lesion is confined mainly to the rectum and descending colon, the small intestine being but rarely involved, while the actual destructive process goes on mainly in the submucosa, forming ulcers with undermined edges.

French Journals.

Two Cases of Cyst of the Round Ligament.—Lebesque reports these cases. The first patient was a woman, fifty-two years old. For ten years she had noticed the presence of a small tumor at the level of the external orifice of the right inguinal canal. The tumor had progressively increased in volume without causing acute pain. There was in the subpubic and right inguinal region a tumor the size of an orange. It measured vertically 13 cm., horizontally 12 cm., and its limits were the median line, the right labium majus, the crural region, and the edge of the pubis. The tumor was fluctuating. The operation consisted in opening the inguinal canal and in excision without ligature of the tumor. The other tumor occurred in a woman of twenty-one years. These tumors, which proceed from an incomplete obliteration of the inguinal canal, are rather rare.—*Journal de Chirurgie et Annales de la Société Belge de Chirurgie*, October–November, 1901.

Considerations Concerning Supravaginal Hysterectomy.—Verdelet states that in supravaginal hysterectomy if the stump is put back into the abdomen when hæmostasis is not perfect, there will form a small hæmatoma which will be easily infected from its proximity to the intestines, and in consequence there will be a rise in temperature sometimes eight days after the operation. Sometimes there are analogous occurrences after the enucleation of fibromata, especially in the case of intraligamentous fibromata, for here complete hæmostasis is almost impossible. This febrile manifestation coincides with the development of an infection secondary to hæmatoma, giving place to that of pelvic peritonitis, to pelvic cellulitis, or to phlebitis, which cause a delay in the recovery. Besides these infections, there occur sometimes consecutive neoplastic alterations in the stump (recurrences of fibromata, of carcinoma, etc.). These facts ought to call attention to the precautions which should be observed in the operative technique of supravaginal hysterectomy. The surface chosen for attachment should be absolutely bloodless.—*Gazette de Gynécologie*, November 1, 1901.

Professional Neuritis.—According to Baraks, predisposition stands in the first rank of the etiological conditions which favor the development of professional neuritis. Although this is difficult to define clearly, it certainly exists. Professional neuritis is exceptional at the extremes of life; it is seen especially between the age of twenty-one and thirty-five years. It predominates in men, though it is also seen in women. Compression is the essential cause. Fatigue, compression, and stretching are the three important factors that cause this trouble. Clinically, a neuritis may be considered professional only when it is caused by professional work itself. There are three classes: neuralgias, paralyses, and spasms. It is in the professional paralyses that all of the habitual morbid symptoms of neuritis in general are found. The spasms are rarely observed. Diagnosis of these troubles is simple and seldom presents any difficulty. Treatment is especially prophylactic.—*Gazette des Hôpitaux*, November 7, 1901.

Five Cases of Rupture of the Spleen in Patients Suffering from Malaria.—Bonnet draws the following conclusions from the cases which he reports: 1. Rupture, called spontaneous, of the spleen during an access of intermittent

or pernicious fever is possible. It is favored by the softening, the diffluence, the enormous tumefaction, the congestion, and the rapid increase of the splenic pulp which may distend the capsule and cause it to rupture. 2. Sometimes this capsule is thin with a normal appearance; sometimes it is thickened, sclerosed, and has lost part of its elasticity. It yields and bursts from the pressure of the contents at those points where the thickness and resistance are least. 3. The adhesions of the malarial spleen to the diaphragm and to the stomach, which are so frequent, favor rupture, it may be from the pulling caused by the adhesions, it may be by the loss of mobility of the spleen, which is thus greatly exposed to traumatism. 4. The alterations, the hypertrophy, and the friability of the large spleens, observed in chronic malaria, were the predisposing causes of rupture in four of these cases reported. 5. In three cases there were tears at the hilum in the shape of a star. In one case the rupture appeared to result from a sort of contre-coup. Slight traumatism may cause a rupture. 6. There is one observation relative to rupture after a copious repast, which presents a certain interest from the medico-legal point of view. 7. In one case, splenectomy would have saved the life.—*Bulletin de l'Académie de Médecine*, November 5, 1901.

Annals of Surgery, November, 1901.

Genital Tuberculosis with Special Reference to the Seminal Vesicles; Report of Two Cases of Spermatocystectomy.—H. H. Young gives a careful resumé of the literature of this condition and a table summarizing the results of some thirty-five operations for removal of the seminal vesicles for tuberculosis associated with testicular disease. The part removed was one testicle (or epididymis) twenty-three times, both testicles five, one seminal vesicle twenty-three times, both seminal vesicles eleven times, a portion of the prostate five times. Of immediate results 13 were good with no fistula, a fistula resulted in 14, two were in bad condition, and the state of affairs is not mentioned in three. Of nineteen patients whose subsequent history was ascertained five died, ten were well, and recurrences had occurred in four. Only eight patients were followed over one year; of these two died of pulmonary tuberculosis, two had perineal fistula, four were cured. In only one of the five fatal cases was there any record of pulmonary involvement before the operation, and in only four cases was there any involvement of the bladder, and in three of these cases it was very slight. No history of kidney disease was recorded. The operative indications may be summarized as follows: Epididymectomy with high resection of the vas deferens is the operation of choice. Castration should be confined to cases where the testicle proper is involved, or the serotal disease is extensive. Double castration should be avoided if possible, a portion, at least, of one testicle being left, even with the risk of local recurrence of the disease. Operations upon the seminal vesicles and prostate should only be done after removal of the testicular foci has failed to arrest the progress of the disease in these organs, and it has spread to the bladder. Serious involvement of distant parts—pulmonary, urinary, osseous, etc.—does not contraindicate operation, especially since the more exact methods of using cocaine have made general anæsthesia unnecessary. That remarkable disappearance of extensive tuberculosis of the prostate, seminal vesicles, bladder, kidneys, lungs, etc., may follow the simple removal of the testicular foci seems abundantly proven.

Skin-Grafting in Complete Stenosis of the Larynx.—A. J. McCosh reports the case of a boy of fourteen years in whom laryngo-fissure had been done for papilloma. Tracheotomy was done at the same time and a tube had been worn since. The epiglottis was bound down over the laryngeal entrance by cicatricial tissue. Further examination showed that the windpipe was completely obstructed from the epiglottis down to the second tracheal ring. Several operations were necessary for the excision of all the cicatricial tissue and the reopening of the breathing passage. Finally the canal was grafted from the first tracheal ring to within half an inch of the glottis by a Thiersch's graft taken from the thigh. This was rolled around a rod of gauze covered by rubber tissue, which was inserted with the raw surface of the graft against the bleeding surface of the new tracheal canal. The section grafted was about three inches in length. Through the glottis a silk thread was carried, emerging through the mouth. The graft "took" throughout its entire length, and some three weeks later the anterior wall of the windpipe was formed by dissecting loose the skin edges of the wound and uniting them by suture in the median line, a tube the size of No. 22 (F.) being inserted, its lower end resting against the tracheotomy tube and its upper end projecting through the mouth, strings being attached to each end and fastened to the patient's neck and chest. The tube was replaced by a series of others of gradually increasing caliber. For some time the patient has been wearing an intubation tube and through this respiration is comfortably maintained, the tracheal opening being closed by a pad of gauze. As there are no arytenoids or projections to maintain the intubation tube in place, it is occasionally expelled, and is sometimes not replaced for hours, during which time the boy breathes through his larynx. It is deemed wise to insist on his wearing an intubation tube, at least intermittently, for some months longer, until all danger of recontraction of the glottis above the site of grafting has passed. There is no question, however, that at the present time he could dispense with both the tracheal opening and his intubation tube. At a later date the tracheal fistula will be closed.

Acute Intestinal Obstruction Following Appendicitis a Report of Three Cases Successfully Operated Upon.—The cases are reported by L. W. Hotchkiss who believes that they show the value of the following procedures under given conditions: (1) The great utility as well as necessity for the free use of the decinormal salt solution, whether into the subcutaneous tissues, the rectum, or the veins, both during as well as after operation, as a guard against extreme shock. (2) The great value of free incision into over-distended coils of gut (*a*) in order to relieve upward pressure upon the diaphragm, and the disturbance of respiration and circulation consequent upon it; (*b*) to relieve the congested intestinal vessels, and to diminish the size of the enormously distended coils so that they may be handled without injury, and the obstruction more easily located and dealt with, as well as at the same time to drain away from the interior of the gut a great quantity of stagnant fluid before it can reach the absorbing surfaces of the intestine below the obstruction. (3) The practicability and desirability of closing the abdominal wound without attempting to drain the peritoneum, and the leaving within the cavity sufficient saline solution to float the intestines and assist, perhaps, in their rearrangement. The postoperative treatment of these cases, especially if they have been brought late to operation, is of vital importance, and upon its intelligent and diligent application the patient's fate depends. The three measures which are essential are simple but generally effective. They are: (1) The persistent and intelligent use of the stomach-tube, with lavage. (2) Early and, if necessary, the repeated administration of saline purges in concentrated solution, and introduced through the stomach-tube if retained no other way. (3) The use of the rectal tube for the relief of gas, and the patient and persistent use of high enemata. These three measures intelligently, patiently, and perseveringly employed, together with absolute abstention from the use of morphine, no matter what the temptations may be to use it, constitute the tripod upon which rational and effective treatment is based, and upon the intelligent use of which the life of the patient often absolutely depends.

Foreign Bodies Accidentally Left in the Abdominal Cavity.—A. Schachner has collated 155 cases. He draws conclusions as follows: (1) So long as surgery continues an art, so long will foreign substances continue to be unintentionally left in the abdominal cavity. (2) That the recorded cases are not representative of the true frequency of this accident. (3) If the foreign body is of an aseptic character, nature endeavors to care for the same by encapsulating the foreign substance primarily in a fibrous exudate interspersed with leucocytes, and secondarily enclosing it by the contraction of adhesions between the different abdominal viscera or the viscera and abdominal wall. (4) In the spontaneous expulsion of a foreign body from the abdominal cavity, nature seeks exit through points of least resistance, which are either the alimentary tract or an imperfectly united wound, or less frequently through the reopening of an apparently well-organized cicatrix. (5) A foreign substance may remain quiescent for years in the abdominal cavity. (6) The disturbance which a foreign body creates in the abdominal cavity depends upon its sterility, size, character, *e. g.* regularity of outline and presence of sharp or pointed surfaces; density, point of location, individual tolerance of the peritoneum, and behavior of the individual. (7) The symptoms of a foreign body in the abdominal cavity may vary from *nil* to that of the most violent intra-abdominal disturbance. (8) The symptoms not infrequently suggest a low and protracted form of sepsis or an ileus. (9) Unexpected circumstances, unusual complications, and diverted attention explain many of these accidents. (10) While the counting and recounting of sponges and pads before and after an operation by one or more individuals should and always will be a most important feature in the prevention of this accident, yet the cases are numerous where the accident occurred notwithstanding this count by one and even two nurses or assistants. (11) The plan of attaching tapes or threads to pads and instruments has received the recommendation of many operators, bu

the fallibility of these as clearly proven as the former (12). In restricting ourselves to the smallest number of pads, sponges, and instruments, we adopt a system of simplicity that must appeal to all as one of the most important elements in the avoidance of this accident. (13) We can only hope to reduce these accidents by the observance of the highest degree of simplicity, system, and watchfulness. (14) If the surgeon at the close of the operation asks for a count of sponges, and this is made, and an assurance given that all sponges and pads are present, his responsibility on this point ceases; for it is neither prudent nor fair that he should leave the most important part to do duty that justly belongs to the nurse. (15) The real factors in the avoidance of this accident are the recognition of system, simplicity, and watchfulness to the most exacting degree. (16) At the bottom of most of these accidents, we find a diverted attention, a defective system, or a dangerous degree of complexity. (17) We are obliged to conclude that to a certain extent the surgeon is responsible for things about the operation, and after that the responsibility must rest elsewhere. (18) No hard and fast rules can be made regulating the responsibility in every case, but each must be decided on its own merits, and the responsibility fixed accordingly. (19) There are risks that the patient must assume and that cannot be rightly transferred to the operator. (20) In other vocations, it is reasonable to assume that unless properly prepared one should not act; but in surgery one is occasionally compelled to act, even though it is known that he is not prepared.

The Practitioner, November, 1901.

Clinical Forms and Diagnosis of Bright's Disease.—R. T. Williamson gives the diagnosis of acute nephritis, chronic parenchymatous, and chronic interstitial nephritis with their sub-divisions. Mistakes in diagnosis are chiefly made: (1) Through the examination of the urine having been omitted; (2) Through a diagnosis of Bright's disease having been based on one symptom only, the presence of albumin in the urine, cases of albuminuria, accidental, functional, or pathological, have thus been mistaken for Bright's disease. The author gives details as to the diagnosis in each case.

Uræmia.—J. R. Bradford reports his experiments in regard to the origin of uræmia, but concludes that the only securely established facts at the present time are that mere retention of the normal constituents of the urine is not capable of producing uræmia; that in uræmia there is an extensive disintegration of the proteid tissues of the body; and that, although in many cases of uræmia there is in the final stages some suppression, partial or complete, of the urinary secretion, this is by no means invariable, and that certainly fatal uræmia may be seen with an abundant secretion of urine. Clinically uræmia may be divided into the acute, the chronic, and the latent forms. Dyspnœa the author considers the most constant symptom; it is also frequently an initial symptom, and it may be almost the only one even in fatal cases.

Renal Disease and the Circulation.—W. H. Broadbent enumerates the changes found in the blood vessels and heart in renal disease. The therapeutical indications are immediate and free venesection on the occurrence of uræmic convulsions, and the reduction of intravascular pressure. The best means known to him of exercising a definite influence on unduly high intra-arterial pressure is through mercurial aperients. A dose of calomel, three to five grains, will often avert impending convulsions, or prevent their recurrence, will relieve the headache, stupor, and twitchings, and may prevent uræmic paroxysmal dyspnœa in advanced kidney disease. So also a single grain of blue mass, or mercury with chalk, with rhubarb or colocynth and hyoscyamus, once, twice, or three times a week, according to the degree of tension in the pulse, exercises a favorable influence in the early stages of chronic Bright's disease, both on the symptoms and on the course of the disease.

Mental Conditions Associated with Bright's Disease and Uræmia.—Theo. B. Hyslop says that any defect in the renal system associated with arterial degeneration and a tendency to cardiac failure is apt also to be attended by brain failure. Renal cirrhosis is thus frequently associated with adhesion and thickening of the dura mater. The pia mater is also apt to be thickened and opaque, and in some instances adherent to the cortex cerebri. When this is the case, the lymphatic or vascular circulation is so impaired that symptoms of cerebral and mental degeneration appear. Renal disease, therefore, is associated with insanity in two ways: (1) Acute, transient, delirious mania, an acute toxæmia, or uræmic insanity; (2) A progressive cerebral degeneration, with chronic renal disease as the primary cause. In this type, the mental symptoms during the earlier stages vary from a mild dementia to mania or delirium. In due course, however, complete dementia results, not unlike paralysis of the progressive type known as general paralysis of the insane.

Occurrence of Nephritis in Certain of the Specific Fevers: Its Prognosis and Treatment.—F. Foord Caiger says that in the treatment of a case of scarlet fever the liability to nephritis should constantly be borne in mind. In the early stages of the fever, a temperature as low as 50° F. can be well tolerated, but from about the beginning of the second to the end of the fourth week, a higher temperature is desirable; wool should be worn next to the skin, and warm baths should be given daily to encourage the action of the skin. In diphtheria, definite nephritis rarely supervenes; though albuminuria, often of considerable degree, is present in a large proportion of attacks. The presence of albumin may usually be taken as an indication of severity of the disease, and does not represent, as in the case of scarlet fever, an additional source of danger. In the course of typhoid fever, albuminuria is of common occurrence. It is very rare that symptoms of renal impairment are sufficiently pronounced to justify the term nephritis.

Skin Eruptions in Bright's Disease.—J. J. Pringle discusses the various skin eruptions which are clearly secondary to Bright's disease. Pruritis is very apt to be present in all degrees of severity. Urticaria is rare and doubted by many. Eczema is not so frequent as many suppose. The author agrees with Thursfield, who writes, "There is nothing to show that eczema is more common in patients suffering from albuminuria than in others." Yet there is a form of papular eruption, strictly localized, which Merk considers pathognomonic of Bright's. *Erythema papulatum uræmicum* is the most characteristic and interesting skin affection, the association of which with Bright's disease is most clearly established. When severe, it occurs in the last stages of the disease, but cases of mild type and transient duration may occur in the earlier stages. *Generalized bullous eruptions* are rare; *general exfoliative dermatitis* may in some cases be attributed to chronic nephritis; *purpura* certainly occurs; *boils, carbuncles*, and *œdematous lesions* are also common, as in diabetes. Neither urea nor uric acid is the toxic substance at play in the causation of these skin eruptions. Whatever the toxins are, they probably act through the vasomotor and trophic nerve systems.

Revue Médicale de la Suisse Romande, September 20, 1901.

The Use of Large Doses of Antidiphtheritic Serum.—E. Thomas holds that large doses of the serum should be injected on the first day of treatment, if the case is a serious one, or if there is croup. On the second day the attitude should be one of expectancy and watchfulness for the results of the treatment. Forty c.c. should be considered the maximum amount to be given the first day. No harm results from this dosage, yet in cases of albuminuria, or positive nephritis, great prudence should be exercised.

A Clinical Form of Primary Acute, Infectious, Malignant Endocarditis.—L. Revilliod reports a case of endocarditis characterized by two chief symptoms: 1. Slight fever, not above 30° C. (102.2° F.), rebellious to treatment, and giving rise to no subjective sensations. 2. Pallor of the skin which persists in spite of the fever. This is the first stage. Later come slight lancinating pains in shoulder and arms, and shortness of breath without dyspnœa or palpitation. Stethoscopic signs appear, the spleen is enlarged, the urine is scanty and loaded with urates and uric acid. In the third or terminal period, there are cachexia, feebleness, emaciation, and finally serous effusions in the thoracic cavity. The whole course of the disease may take four months or more.

The Influence of Diet on the Re-establishment of the Cardiac Functions.—J. L. Prévost and F. Battelli found that when animals were killed by asphyxia from occlusion of the trachea or by means of chloroform, the heart was arrested in diastole. If artificial respiration was produced, and massage applied to the heart, the rhythmical beating of the heart returned, providing the animal had been killed while digesting a mixed meal of meat and bread. In fasting animals, there were produced permanent fibrillary tremors. A diet of albuminoids only produced the tremors in some cases preceded by rhythmic beatings. Fat caused the tremors, hydrocarbons rhythmic contractions which were not constant. It may therefore be asserted that a mixed diet has the most favorable influence on the restoration of the cardiac function after asphyxia.

Proceedings of the Fourteenth Annual Meeting, Held in Richmond, Va., November 12, 13, and 14, 1901.

Second Day—Afternoon Session.

Results Obtained in Sixty Operations for Prostatic Hypertrophy, with Demonstration of a New Cautery Incisor.—Dr. HUGH H. YOUNG of Baltimore, Md., read a paper on this subject.

Stimulated by the work of McGill, Belfield, and others, and having performed prostatectomy in ten cases without a death, the author encountered some cases of prostatic enlargement in very old men which seemed to be entirely beyond the reach of a radical operation. On account of these cases he began a trial of the Bottini operation, and the present paper reporting sixty cases is intended to show a comparison of the two methods, and the results he has secured. These sixty cases were classified as follows: Prostatectomies, 15; Bottini operations, 40; miscellaneous operations, castrations, etc., 5; total, 60. Taking the prostatectomies, 12 were suprapubic, and 3 perineal. The ages were 4 between 65 and 67, 2 between 60 and 65, 5 between 55 and 60, 2 between 50 and 55, and 2 between 48 and 50. The condition was fairly good in all but 3 cases. Calculus was present in 5 of the 15 cases, and 6 had led catheter lives. In seven of the fifteen cases the hypertrophy was very large: in three it was merely a small pedunculated middle lobe. In 11 cases complete enucleation of the entire prostate was made. In some cases the tumor removed was extremely large. Results: fifteen operations, with two deaths. Both of these deaths should not have occurred. One patient was undoubtedly septic, had pus kidneys, and should not have been operated until later. In the other case, death seemed to have resulted from an infection of the breast after submammary infusion. Of the thirteen cases still alive, twelve have gone for periods between six months and three and a half years since operation. Of these twelve, ten may be classed as cured, having no prostatic obstruction, and normal urination. Two are perfectly cured as far as the prostate is concerned, but suffer from cystitis and a contracted bladder, which render urination frequent, though much better than before operation.

Taking the Bottini operations, 40 in number, 6 have not been followed. The 34 remaining operations were performed on 31 patients, 3 patients having 2 operations each. The ages were as follows: Over 80, 3 patients; between 75 and 80, 3 patients; all of the above cured. Between 70 and 75, 9 patients; between 65 and 70, 6 patients; between 60 and 65, 6 patients; between 55 and 60, 4 patients. In all, 18 patients over 67 years of age; whereas, among the prostatectomy cases, none were over 67 years of age. Of 15 cases over 70 years of age, all are alive and well. In 12 of the 31 cases, the general condition was very poor. The size of the prostatic hypertrophy was very large in 17 cases, moderate in 8 cases, and slight in 6 cases. All forms and grades of prostatic hypertrophy were represented from a large, soft, succulent prostate, to the small, sclerotic, not enlarged prostate. Results: In all prostatic cases, the ultimate results depend not entirely upon a cure of the prostatic obstruction, but upon the condition of the bladder which persists. If a cystitis is present, it may lead to very frequent urination. If the bladder is markedly contracted, it also may lead to frequent urination, although all obstructive symptoms are absent. Then, again, if the prostate or bladder is of the irritable class, this, too, may simulate frequency from prostatic obstruction, so that as to ultimate results the condition of the bladder as well as the prostate has to be considered. In Dr. Young's experience, both after prostatectomy and after Bottini operations, cystitis is likely to persist, although generally very much improved in most of the cases. Of the thirty-one Bottini cases which have been followed, sixteen still have bladder infection, and others have not been heard from. In 10 the capacity of the bladder is diminished, and in some cases markedly contracted. In two cases, although all obstruction is removed, there is no residual urine present and no infection. The irritability of the bladder persists, which at times renders micturition extremely frequent, although prostatic obstruction is absolutely cured. It may be said that these conditions follow all prostatic operations, and demand that the bladder be systematically treated for some time after all prostatic operations.

As to the prostate, of the thirty-one cases, three died. Two of these cases died four and five weeks after the operation from uræmia, and were undoubtedly due to the presence of pus kidneys, and can hardly be attributed to the operation. Death in the third case was directly due to sepsis, which the autopsy showed was attributable to two of the cuts penetrating the capsule of the prostate. In this case the prostate was greatly hypertrophied, and following the advice of certain authors the operator had made a cut of four and a half centimeters. But autopsy showed that this was too long, and that a periprostatic abscess had resulted. The author declared that in the future he would never make an incision longer than three and a half, or, at most, four, centimeters, and considered this entirely sufficient, even for the greatest hypertrophies. Of the twenty-eight cases which lived, twenty cases were not too recent, and have been heard from. Of these, seventeen were cured, two improved, and one unimproved. Of the eight cases, too recent or unheard from, in all the immediate result was good, and prospects for ultimate result first-class. As to the general condition, in all of the twenty-eight cases the patients were greatly improved, barring perhaps two cases, who, although relieved of prostatic obstruction, suffer from a slight dribbling of the urine. Both of these cases were of slight enlargement, and the author thinks that the dribbling would not have resulted, had he been able to use a smaller blade, such as the new instrument contains. The results, therefore, after the Bottini operation, seem to be perfectly satisfactory. Of thirteen patients who used catheter before the operation, all have been relieved of this and urinate freely.

In discussing the Bottini operation, the author brought out the point that the instrument devised by Freudenberg, while an admirable one, should have more than one blade, so that the operator might have choice as to the depth of cut, which should be made in accordance with the size of the prostate. The beak of the instrument is much too sloping, so that several cases have occurred in which the beak has slipped into the urethra, and caused dangerous hemorrhage, with sometimes death. In order to correct this and other defects, the author has devised an instrument which, like the Freudenberg instrument but with four interchangeable blades, can be used according to the case, whether the prostate be large or small. With this instrument he has now performed nine operations, using in those cases all of the blades but one, and he can testify to the great service of the ability to use some discretion in the size of the blade that is employed in accordance with the prostatic hypertrophy. The instrument seems necessary for cases of small sclerotic prostates, which, although producing very serious obstructive symptoms, are so small that the ordinary Bottini operation is dangerous. By using blade No. 1 or blade No. 2 of the new instrument, the operation can be done with perfect safety, and a cure resulted in all cases.

Suprapubic Prostatectomy.—Dr. FLOYD W. MCRAE, Atlanta, Ga., followed with a paper on this subject, in which he advocated the early resort to this method of treating enlarged prostate rather than palliative measures or the seemingly simpler operations of suprapubic fistula, vasectomy, orchidectomy, or the Bottini operation. His reasons were that the seemingly simpler operations are

followed by mortality disproportionate to their magnitude; that the relief obtained from them is frequently slight and temporary; that the pathologic conditions were not infrequently aggravated, especially by the Bottini operation. He reported three complete prostatectomies done since May, 1901. The point of originality claimed for the operation is the method of draining. He puts in a retention catheter through the urethra, and closes the bladder and overlying tissues snugly around a parachute drainage tube, made of a soft rubber rectal tube, with a single opening at the end, by making four longitudinal slits beginning about one-quarter to three-eighths of an inch from the end of the tube, each slit about an inch long and equidistant from each other, around the circumference of the tube. The four sections are then approximated above and below, by means of a small rubber band put through in the form of a Halsted suture with a large needle. As these sutures are drawn taut, the sections are approximated and the ends flared out somewhat like a parachute. When the bladder is closed, this tube is drawn up so that the flared portion is in firm contact with the anterior bladder wall. The overlying tissues are then closed snugly around the tube and one silkworm gut suture is put through the tube flush with and through the skin to hold it in position. The flaring of the tube enables the surgeon to draw it firmly against the anterior bladder wall, and by means of the suture put through it and the skin it is prevented from protruding too far into the bladder, avoiding the disagreeable contraction that always takes place in that organ if the tube is too long. By this method of drainage, the outer ends of the catheter and tube are then put into a urinal which is kept between the legs when the patient is lying on the back, or in front of the thigh when the patient turns from side to side. The advantages claimed for this method of drainage are that the patient is kept absolutely dry and is allowed to turn freely in bed, lying on the back or either side. He reported three operations done by this method since May, 1901, together with a complete pathologic report by Dr. H. F. Harris, pathologist, Atlanta College of Physicians and Surgeons, of the specimens removed. The specimens proved to be "leiomyoma," and "leiomyo-adenoma," with increase of connective tissue as the result of chronic irritation. The irritation noticed in the large specimen evidently followed a Bottini operation done a few months previously, and was associated with phosphatic stone. The patient operated upon in May is now entirely free from bladder irritation, passes a good stream, projecting four and a half to five feet by measurement when the bladder is moderately distended. Bladder holds, under ordinary conditions, eight ounces by actual measurement, and is capable of holding considerably more. Case 2 is still wearing a McGuire plug, but passes urine readily per urethram. Case 3 is practically well, the suprapubic opening closed, bladder clean, and urine passing freely through the urethra without residue.

Median Perineal Prostatectomy; Total Removal of the Prostate Gland.—A paper with this title was read by Dr. ALEXANDER HUGH FERGUSON of Chicago. He referred to the work of Nicoll, Alexander, Symes, and von Dittel, raising objections to each of the methods followed by those gentlemen. He then proceeded with illustrations and the exhibition of instruments to describe his own operation, which is as follows: "The patient is put to sleep with chloroform, and placed in the extra-lithotomy position. The prostatic depressor is inserted into the bladder through the urethra, and handed over to a trusty assistant. A sponge is pushed into the rectum to prevent the escape of liquid fæces. The middle finger of the left gloved hand is then introduced into the rectum and pressed against the urethra at the junction of the membranous and prostatic portions; a long narrow-bladed knife is passed into the perineum through the raphe in the median line, two inches in front of the anus, until it reaches near to the tip of the finger in the rectum, and with one stroke all the structures are cut through to the prostate, without injury to the urethra, prostate, rectum, or anal sphincter. The surgeon should refrain from doing this in his first cases. The skin incision is now enlarged, if necessary, for the introduction of two fingers. Place suitable retractors, one on each side, into the wound, and by blunt dissection expose the prostate, and with the depressor in the bladder, it is forced into the perineal wound. Open the capsule with knife or scissors in a transverse direction sufficiently to admit one or two fingers. Place the retractors within the capsule. This is important, because traction made on them drags the gland still farther into the wound and holds it firmly while enucleation and extirpation are being performed. It is experienced that by traction from below and depression from above, the prostate is fixed, within easy reach, for its entire removal. Enucleate with the finger and bite away the portions thus liberated with the prostatic forceps, until by piecemeal the prostatectomy is completed. No effort is made to save the posterior portion of the prostatic urethra. Indeed, injury to it cannot be avoided when the entire gland is removed. While morcellement is in progress, it is advantageous to advance the retractors within the capsule, and introduce the middle finger into the bladder. The forceps can be rapidly thrust between the two fingers to the object to be removed by them, without any danger to the surrounding structures, for when the instrument is closed, its end is perfectly smooth and round. The lateral lobes can be reached to any extent without damaging the mucous membrane of the bladder, and prostatic projections of the middle lobe into the bladder are detected and removed without difficulty. Flush out the bladder very thoroughly with a weak antiseptic solution. A large stream of water must be used, for the ordinary irrigating toy generally employed only does harm. Mop out with gauze any water that is in the bladder and wound, and introduce a drainage tube, surrounded with iodoform gauze, through the wound into the bladder. A couple of horsehair stitches close the part of the skin wound not occupied by the tube, and at the same time prevent the gauze from coming out too soon. Remove the sponge from the rectum, place a comfortably firm dressing over the perineum, and let it be held by a T-bandage. Now, attach a long rubber tube to the external end of the drainage tube, and the toilet of the operation is finished.

"If the patient's urine has been scanty or should he show depression or shock, then it is better to introduce two or three pints of normal salt solution, at a temperature not less than 115° F., beneath the skin, while he is still in the operating room, than to wait until he is taken to his bed."

The author reported six cases of complete prostatectomy, four cases of removal of the middle lobe alone, and four cases of tubercular inflammation of the vas deferens on each side in the vesiculæ seminales and prostate. In one of those the prostate was not involved on the bladder surface, but it was entirely removed.

The advantages of the operation are: (1) That it is the most direct route to the organ, and that the prostate can be removed without injuring any important structures. (2) That by the method above described the operation is easily performed. In all those cases in which the gland has been repeatedly inflamed, it makes it more difficult to operate, but not as difficult even then to remove the prostate from below as to do the suprapubic operation: (3) The removal of the gland piece by piece enables one to work through a small opening and prevents the bruising of the surrounding parts by the finger which is accompanied with the removal of the gland *en masse* through the peritoneum; (4) Hemorrhage is avoided, so long as one is careful to work within the capsule. The hemorrhage in suprapubic prostatectomy or in the combined method is often very alarming. On one occasion the writer had to leave pressure forceps on blood vessels and pack the bladder tightly with gauze twenty-four hours. The patient nar-

rowly escaped death from both hemorrhage and sepsis. Sepsis and intoxication from pus and fœtid urine coming in contact with the prevesical tissues and wounded and raw surfaces within the bladder are great sources of danger in the suprapubic operation. The bladder may be opened in two stages, it is true, and the prevesical space thereby greatly protected; but the traumatism of the bladder over the prostate, even though done with a cautery knife, furnishes an opportunity for sepsis. Perineal drainage after suprapubic prostatectomy is not as complete as when the prostate is attacked from below. It is found by the writer that the danger from septicæmia is not at all prominent after perineal prostatectomy, and so far has given no anxiety whatever. There is less danger of uræmia. The operation takes a shorter time, the anæsthesia having therefore less effect upon the kidneys, and a minimum opportunity for sepsis makes it easier for the kidneys to perform their functions. Uræmia is always to be dreaded, irrespective of the operation performed. When pyelonephritis or renal sclerosis is present, the shock and the anæsthetic largely contribute to the onset of uræmia. The suprapubic operation is accompanied with far more shock than the author has found following perineal prostatectomy.

Lastly, the results in these six cases of complete prostatectomy for hypertrophy, and four incomplete, and four for tuberculosis, are better than the writer has ever obtained by the suprapubic route.

Third Day—Morning Session.

Foreign Bodies in the Oesophagus.—Dr. JOHN W. LONG of Salisbury, N. C., followed with a paper with this title. The author stated that this accident occurred usually in children and lunatics. It is always possible when a patient is under an anæsthetic, and even food may become impacted in the œsophagus. The presence of a stricture, pouch, or malformation increases the liability to this accident. A foreign body in the œsophagus carries with it both immediate and remote dangers. If lodged high up, there will be dysphagia, retching, and sometimes suffocation, as in a case seen by the writer two years ago, in which an inch screw entered point downward the upper end of the œsophagus of a three-months-old infant, and impinged upon the trachea. When the foreign body is lodged lower down, the danger is more remote and less easily remedied. Unless removed, foreign bodies almost invariably penetrate or ulcerate into some important viscus, as the pericardium, aorta, mediastinum, the pleura; the longer the object remains *in situ* the greater the danger incident to its removal.

After calling attention to the special anatomy of the œsophagus, the author mentions the different methods of removing foreign bodies from the œsophagus. He condemned emetics for the removal of foreign bodies in the œsophagus, except in cases where the nature of the object is not liable to do violence to the œsophagus. Many objects are removed by manipulation through the mouth, either by extraction, or are pushed into the stomach. In one case reported by the author a piece of meat lodged in the gullet of a woman, fifty-seven years of age, which was with some difficulty pushed into the stomach. He called special attention to the fact that unduly prolonged or rough manipulations through the mouth are dangerous—even more so than œsophagotomy.

He reported two cases in which a penny whistle was lodged low down in the œsophagus opposite the fourth dorsal vertebra in children four and seven years old respectively. In both instances the foreign body was removed by external manipulation, although the body was well down within the intrathoracic portion of the œsophagus. Removal of the foreign body was done under chloroform. He also reported one case of an open safety-pin lodged low down in the œsophagus of an infant, forty-six days old. The pin had been *in situ* eighteen days when the case was seen by him, and by means of an œsophagotomy the pin was easily removed.

He called attention to a departure from the usual plan of feeding these patients. In this case the baby was put immediately to the breast. All of the patients recovered. In the three instances the metallic substances were discovered by means of the *x* ray. The author exhibited radiographs showing these foreign bodies *in situ*.

Gunshot Wound of Abdomen.—Dr. JOHN C. WYSOR of Clifton Forge, Va., reported a case of gunshot wound of the abdomen; the thirty-eight caliber ball entered about three-quarters of an inch above the left anterior superior spine of the ileum. Patient was anæsthetized fifteen hours after the receipt of the wound, having been transported a long distance. The author first enlarged the wound in the skin, and with his finger as a probe followed the track of the bullet until he felt the opening in the peritoneum. He then made an incision in the median line below the umbilicus, which was afterwards extended from a little above the navel to near the pubes. The omentum was very short, not reaching as low as the umbilicus, and the coils of intestines presented immediately under the incision. The first knuckle picked up showed two perforations, which were immediately cleansed and closed with Lembert sutures, using fine chromicized catgut, and he continued to close the openings as he came to them until he had sewed up nine perforations. Following the gut still further, he found a portion seven or eight inches in length in which there were six more perforations. As some of these openings were very close together, he feared that in repairing them he might constrict the gut, or that there might be subsequent sloughing. He therefore excised that portion of the intestine, doing an end to end anastomosis by means of a Murphy button. Recovery was uninterrupted.

Penetrating Wounds of the Abdomen.—The author of this paper was Dr. E. D. FENNER of New Orleans, La. The histories of six laparotomies for penetrating wounds of the abdomen were detailed, and statistical tables of 152 cases operated on at the Charity Hospital presented.

Case 1 was a stab wound of the abdomen, omentum protruding. Excision of omentum; laparotomy; recovery. Case 2 was a gunshot wound of the left lumbar region, penetrating the abdomen. There were three perforations of the colon, and a graze wound of the stomach. Laparotomy; enterorrhaphy; recovery. Case 3. Gunshot wound of right buttock; penetrating abdomen, one perforation of bowel; one of bladder. Laparotomy; enterorrhaphy; suture of bladder; recovery. Case 4. Gunshot wound of left hip; eight perforations of intestine; laparotomy; enterorrhaphy; recovery. Case 5. Incised wound of abdomen; escape of intestines; laparotomy; recovery. Case 6. Gunshot wound of thorax; penetrating abdomen; wound of diaphragm, spleen, stomach, liver. Splenectomy; suture of diaphragm, stomach, and liver. Recovery.

The records of the Charity Hospital show that from January, 1892, to January 1901, 152 laparotomies were performed for penetrating wounds of the abdomen with 87 deaths, a mortality for all cases of 57.23. Morton (1880) collected 112 cases with a mortality of 62 per cent. Coley (1898) 105 cases, with a death rate of 67.2 per cent. Of the 152 cases seen at the Charity Hospital 113 were for gunshot wounds, with 78 deaths, a mortality of 69 per cent; 30 were for stab wounds, with 9 deaths, or 23.07 per cent.

The table showed 105 cases of gunshot and stab wounds of the abdomen operated upon, with visceral injuries, of which 74 died, a total mortality of 70.47 per cent. Of these 105 cases with injuries of the viscera, 99 were gunshot wounds, of which 71 died, a mortality of 73.95 per cent.; and 9 were stab wounds, of which three died, a mortality of 33.33 per cent.

In spite of the high rate of mortality shown by these tables, the author does not think they should discourage

the operation. A mortality of 73.95 per cent. from gunshot wounds with injury of the hollow viscera means, in his opinion, that 26 per cent. of these patients had their lives saved by the operation; and a death rate of 33.33 per cent. from stab wounds, with the bowels cut, means that two-thirds were saved from certain death.

Nephro-Ureterectomy.—Dr. J. Wesley Bovee of Washington, D. C., detailed a report of two cases. The first one was a nephrotomy followed by incomplete nephro-ureterectomy for pyonephrosis, adrenal tumor, and pyoureter; extraperitoneal operation; recovery. The second case was nephrotomy followed by complete nephro-ureterectomy for pyonephrosis and pyoureter; extraperitoneal operation; recovery.

After narrating these two cases, the author dwelt upon the indications for nephro-ureterectomy, saying that the principal reason for this operation is tuberculous disease of both these structures.

Dr. George H. Noble of Atlanta, Georgia, read a paper in which he spoke of, and advocated the use of, adhesive straps for the prevention of laceration of the perineum in forceps delivery.

He also described a method of removal of fibroid tumors through the vagina by continued spiral incision.

Report of a Case of Hepatotomy for Biliary Obstruction, with Remarks.—Dr. W. E. B. Davis of Birmingham, Ala., read this paper. The case was the fourth in which he had performed this operation, the first having been done in October, 1898. The operation is indicated in cases of obstruction with enlarged liver, where the gall bladder or ducts cannot be isolated, or the patient's condition from exhaustion and cholemia will not permit of a protracted search for the bladder or ducts, and is intended to bridge the patient over for a radical operation. It will be only exceptionally called for, but it is the only available procedure in such cases. The bile will escape from an incision in the liver, as it does in a cholecystostomy, and after the patient's condition has improved, the stone may be removed from the duct. The operation will be less frequently called for, as the surgeon's experience increases in choledochous operations, as he will then be better able to locate the bladder and ducts so much changed. The operation should also be resorted to in hepatitis, before it has reached the stage of pus formation, if the liver does not rapidly become smaller after drainage of the gall bladder or ducts.

Third Day—Afternoon Session.

Induction of Abortion.—Dr. Joseph Taber Johnson of Washington, D. C., detailed two interesting cases, in which attempts were made to produce abortion. In one case, a medical man attempted to produce abortion at about the tenth week of gestation by inserting into the uterus a No. 8 flexible bougie. Some difficulty was experienced in getting it to pass the internal os, but after persistent effort the instrument was pushed up nearly its entire length, leaving perhaps two inches protruding into the vagina. The bougie was supposed to be coiled up in the uterus. Its expulsion was prevented by a cotton tampon pushed high up in the vagina. A physician informed the writer that when he removed the tampon, the fœtus and a portion of the membranes came away. He was unable, however, with the most diligent search, to find the bougie, and finally came to the conclusion that it must have slipped out, without the patient's knowledge, during one of her many visits to the closet in the night. The second day after the abortion, the patient had a severe chill, followed by a considerable acceleration of pulse and temperature, with gradual but steady increase of abdominal pain and distention. Dr. Johnson saw the patient in consultation, made an abdominal section, and removed the bougie from the peritoneal cavity.

The second case was one of ruptured umbilical hernia, in which several feet of intestine had been out on the surface of the abdomen, and covered with unsterilized cloths and bandages for at least seventeen hours. The patient had had the hernia for fifteen years, and was fifty-seven years of age. The intestines were very dark and very cold and dirty. A thorough cleansing and warming with hot salt solution succeeded finally in getting them and the adjoining skin of the abdominal wound into a tolerably fair condition. About a pound of omentum was removed, which bled in a number of places, from which adherent clots had been detached. The tight rim encircling the protruding gut was incised above and below, and the three feet of intestine returned to the abdominal cavity, which was subsequently filled with hot salt solution. A rather long and difficult operation was then performed for the radical cure of an old umbilical hernia in a very fat abdominal wall. The woman gave every promise of getting well for seven days, then she suddenly grew weak, and collapsed and died on the eighth day, apparently of a general septic peritonitis.

Dr. Southgate Leigh of Norfolk, Va., reported a case in which he did a plastic operation for loss of base of the bladder. He also narrated a case of ovarian cyst in a negro woman, which was complicated by a fibroid tumor of the uterus.

Hernia of the Ovary-Inguinal.—Dr. Wm. P. Matthews of Richmond, Va., reported this case. The patient, Miss I. E., aged seventeen, five feet six inches high, weight 145 pounds, strong and robust, was born with a swelling in each inguinal region which did not occasion any alarm or produce any inconvenience until she reached her fourteenth year, when they began to enlarge and at intervals became so tender as to confine her to bed for two or three days. Pressure on them produced pain and nausea. She never menstruated. The author operated for the relief of the hernia, following the Bassini method. The sac was firmly adherent to the internal ring and to the adjacent part of the canal. The sac was opened, and a tumor, inclosed in several layers of fascia, was exposed, carefully dissected out, and examined.

It proved to be an adenoma of the ovary, though it looked more like a testicle than an ovary. The specimen consisted of four distinct parts: (1) An oval flattened body, six centimeters long three wide, and 1.5 thick; (2) A cystic tube, 5.2 centimeters long, one end of which was dilated. This was joined in part to the body by fibrous connective tissue; (3) Parallel and beneath was another tube which entered the body; (4) Perpendicular to this latter tube was a third tube which also entered the body. Upon section the body showed a grayish-red surface, with one white, well-isolated tumor. The microscopical examination which accompanied the paper was made by Dr. G. Baughman. Examination revealed absence of the uterus. The ovary was removed and the parts closed in the usual manner, and patient left the hospital in three weeks.

Inquiry into her family history revealed interesting facts. Her great-grandmother was an only daughter. She was twice married, and bore children in each union. Of the female descendants of the first marriage there were eight that were never unwell in their lives, and all lived to be over twenty years old. Of the second marriage there was one of the two daughters who was never unwell. Two aunts of the patient have never menstruated, and one has a double reducible inguinal hernia. Five first cousins of the patient have never menstruated, and two of these are ruptured just as she was. One sister of the patient has never menstruated, and has a reducible hernia in the left side, an irreducible on the right. One fact he learned is that these women who have never menstruated have hardly any hair in the axilla and on the pubes and are not troubled by any unpleasant odor from the perspiration.

Dr. George S. Brown of Birmingham, Ala., read a paper in which he described a modified Hodgens splint for the treatment of fractures of the thigh. He also

demonstrated the application of the splint on a negro.

Dr. Chas. P. Noble of Philadelphia, Pa., read a paper on "The Treatment of Procidentia Uteri."

The following officers were elected for the ensuing year: *President*, Dr. W. E. B. Davis of Birmingham, Ala.; *First Vice-President*, Dr. J. Wesley Bovee of Washington, D. C.; *Second Vice-President*, Dr. John W. Long of Salisbury, N. C.; *Secretary*, Dr. W. D. Haggard, Jr., of Nashville, Tenn.; *Treasurer*, Dr. F. W. McRae of Atlanta, Ga.

Cincinnati, Ohio, was selected as the place for holding the next annual meeting. Time, second Tuesday in November, 1902. Dr. Thaddeus A. Reamy was selected as the Chairman of the Committee of Arrangements.

Fifteen gentlemen were elected members of the Association.

NEW YORK ACADEMY OF MEDICINE

SECTION ON SURGERY.

Stated Meeting, November 11, 1901.

John B. Walker, M.D., Chairman.

Partial Gastrectomy for Non-Malignant Tumor of the Stomach.—Dr. William B. Coley presented this case, with the following history: E. C., fifty-five years of age, born in Ireland, farmer by occupation, was admitted to the General Memorial Hospital September 30, 1901. The family history was entirely negative. The patient had always been in good health until the last two or three years, during which time he had suffered more or less from gastric indigestion. During the last six months he had had considerable pain in the stomach, most pronounced soon after eating. Attacks of vomiting had occurred, usually soon after meals, and had gradually become more frequent. The patient had lost about twenty pounds in weight, and his condition had become such as seriously to interfere with his work; hence hospital treatment, with a possible exploratory laparotomy, had been advised. Dilatation of the stomach with gas showed a small tumor in the epigastric region, apparently connected with the stomach. No test was made for hydrochloric acid. Exploratory operation had been performed on October 9, 1901, with the able assistance of Dr. Wm. H. Downes and the house staff. The abdomen had been prepared in the usual way, and just one hour before operation six ounces of black coffee and one ounce of whiskey had been given per rectum. A four-inch incision had been made in the median line, just above the umbilicus, and, on opening the peritoneum, a tumor about two inches in diameter had been discovered under the lesser curvature of the stomach. There were numerous adhesions binding the tumor to the lesser omentum. The peritoneal cavity having been carefully walled off with gauze pads, the stomach was opened and the tumor, together with one-quarter to one-half inch of healthy stomach wall, was excised by means of an elliptical incision. The mucous membrane of the stomach was then sutured by means of a partly continuous, partly interrupted, suture of catgut, and the serous and muscular coats were then united by separate right-angled Cushing's sutures of fine silk. This was re-inforced by interrupted sutures near the pyloric end of the incision. A gauze drain was left reaching down to the incision of the stomach, and the wound otherwise closed with kangaroo tendon and silkworm gut. The time of operation was about one and one-half hours. Very little shock had followed the operation. Six hours afterward, or at 4 P.M., the patient had vomited about one ounce of reddish fluid, and again a similar amount at 5.20 P.M. A saline enema had been given at 6.30 P.M. He had vomited a small amount of a reddish-brown fluid during the night. The temperature on the following day, twenty-four hours after operation, had been 100.8° F., and the pulse 90, falling in the evening to 100.6° and 86 respectively. The patient was put on nutrient enemata every four hours, a stimulating enema of whiskey and saline solution being substituted for the nutrient enemata every four hours. The [illegible] enemata consisted of two eggs, half-drachm of [illegible] ounce of boiled water, and four ounces of peptonized milk; the stimulating enemata of eight ounces of saline solution and one ounce of whiskey. On the second day the patient's temperature had fallen to 99.4° F. and the pulse to 78. He had vomited five ounces of light-green fluid twice during the twenty-four hours. Nothing was given by mouth until the fourth day, when small quantities of boiled water and two-drachm doses of chicken broth were given. On the fifth day, the patient had vomited a small amount of greenish fluid, and feeding by the mouth had been discontinued for two days more. His temperature had remained between 99° and 100.5° F., and the pulse between 70 and 80 during the next four days, the temperature falling to normal on the seventeenth, or eight days after operation. The enemata had been gradually discontinued, and the amount of food by the mouth slowly increased. The patient had continued to do well until the fourteenth day after operation, when, without any apparent cause, the temperature had risen to 101.6° F., but without vomiting or tenderness in the region of the stomach. The following morning the temperature had risen to 102.2° F., and the pulse to 112. Food by the mouth had then been curtailed considerably, and nutrient enemata resumed. The temperature on the twenty-fifth had fallen to normal, but on the twenty-sixth had risen again to 103.4° F. The patient had had a slight bronchial cold at this time, and so it was probable that the temperature was due to this or other causes not connected with the wound healing. The condition had become normal on the twenty-eighth, and since then he had been doing perfectly well. Microscopical examination by Dr. B. H. Buxton showed the tumor to be of chronic inflammatory origin, without evidence of malignant degeneration.

Tumors of the Lachrymal Gland; Kronlein's Operation.—Dr. Franz Torek presented a man, thirty-nine years of age, who had come under his observation for the first time on September 22, 1901. A few months previously he had observed swellings in the region of the parotid gland, and two months previously a swelling above the right orbit. Examination had shown the eyeball to be dislocated downward and forward by a growth, and the conjunctiva injected. In the region of the parotid gland, as well as in front above and below, were swollen glands, and there were other glands in the sternomastoid muscle. The diagnosis was sarcoma of the lachrymal gland, with metastases in the lymphatic ganglia. The man had already been treated with arsenic and mercury. On October 14, he had performed Kronlein's operation, that is, an osteoplastic resection of the outer wall of the orbit. The upper incision was convex upward and the lower one convex downward, so that the periosteal connections could be preserved. The tumor was 1½ inches in its longest, and three-eighths of an inch in its shortest, diameter. Having removed the tumor, the outer wall of the orbit was replaced and the periosteum sutured. The stitches had been removed on the seventeenth day, the wound being healed. Seven days later, the glands had been removed through three separate incisions. Microscopically these glands appeared to be sarcoma, and the gross appearance was the same as that of the lachrymal tumor. The contour of the orbit had been well preserved, and the eyeball was freely movable in all directions.

Spina Bifida; Operation.—Dr. Torek also presented a female infant with spina bifida. The child had been successfully treated by an operation performed on October 7, when the child was eighteen days old. The tumor had been almost spherical, and measured 7 cm. in diameter. The tumor was translucent, tense, and fluctuating. Under chloroform anæsthesia, he had made a longitudinal cut through the exceedingly thin sac. The neck of the sac was very small. On opening it, clear, light yellow fluid was evacuated. No nerve elements were found, showing

that the tumor was of the meningocele. The sac was tied off and excised. Antiseptics were carefully avoided during the operation. The mother was instructed to keep the child constantly in the prone position, and not to use a diaper, thus helping to keep the wound aseptic after operation.

Mixed Cell Alveolar Sarcoma of the Fibula; Amputation Above the Knee; Recovery.—Dr. Arthur L. Fisk reported this case, and presented the patient with the following history:

N. B., male, twenty-one years of age, had been referred to him on September 5 last, because of pain and a swelling in the calf of the right leg, just below the knee, on the outer side. In May last, he had fallen from his bicycle, striking on this knee, and had been laid up for several days. About six weeks ago, he had begun to suffer general pain throughout the lower right leg, and later it had become localized at the upper end of the fibula. Since then there had been a constant dull pain at that place. On examination, there was a slight swelling over the upper third of the fibula, but no signs of acute inflammation, heat, redness, or tenderness. There had been no chills or fever. There was evidence of deep fluctuation on palpation, but no pulsation.

Upon aspiration, bright arterial blood had been obtained, and, when the needle had been withdrawn, the blood had spurted from the puncture. The clinical diagnosis of sarcoma was made, but, to be absolutely sure, exploratory incision had been advised, and had been done on September 11, Esmarch's bandage being used to control the hemorrhage, the tumor when incised showed unmistakably, from its gross appearance, that it was sarcoma. The entire upper third of the fibula was gone; in its stead was a soft granular mass containing some pieces of bone. The entire contents were thoroughly curetted away, and the wound packed. Dr. E. E. Smith, who made the pathological examination, reported that, in gross appearance, the material was seen to consist of bits of spongy tissue, together with many pieces of bone and some blood clots, and that a section of the tissues showed the structure of a mixed-cell sarcoma, alveolar in type. On September 12, amputation of the leg had been performed, just above the knee, by anterior and posterior flaps. No drainage was used, and union was by first intention. The patient had been about in one week, and had been discharged at the end of the second. Since the operation he had gained ten pounds, and was now in the best of health and spirits. Dr. Fisk said that J. Bland Sutton, in the last edition of "Tumors, Innocent and Malignant," writes: A careful examination of the literature relating to sarcoma of bone makes me think that these tumors are rare in the fibula, and certainly do not run a rapid course. This infrequency may be represented in this way. A surgeon may be in active operative practice for a quarter of a century in a hospital in a large town, and may not be called upon to deal with more than three examples.

Dr. A. L. Fisk, referring to the case of spina bifida, said that he had operated upon three cases of spina bifida, and in all of them hydrocephalus had subsequently developed.

Dr. Tobey replied that he had had a similar experience in a previous case, one of meningocele of the occipital region. The patient at the time of operation had been about eight or ten weeks old, and had been apparently cured by the operation; but a few weeks later hydrocephalus had developed, and had ultimately proved fatal.

Dr. W. B. Coley said that he had seen three cases of sarcoma of the fibula. One of these had been operated upon five years ago, and the patient had remained well for a year and a half, and had then developed a sarcoma of the lung. Dr. Lloyd had removed the entire fibula for sarcoma, without amputating at the knee. The patient had been subsequently treated with toxins, and had been reported well three years after operation. The reason for doing this operation was that the tumor was situated near the ankle.

Dr. John B. Walker said that Dr. Hartley had removed a myelo-sarcoma of the inferior maxilla by partial resection of that bone, and the patient had been permanently cured; nevertheless, most surgeons would favor doing a radical operation on sarcoma of the leg.

Dr. Coley said that Bland Sutton held that these myeloid sarcomata showed so little malignancy that it seemed hardly right to class them as malignant growths.

Etiology of Some Unusual Forms of Peritonitis.—Dr. B. T. Tilton read a paper on this subject. As evidence of the relative frequency of the chief causes of suppurative peritonitis, the following series of cases was cited: In thirty-four it arose from perforation of the appendix; in six, from perforation of the stomach; in six, it was due to strangulated hernia; in four, to typhoid perforation of the intestine; in fourteen, the cause was disease of the uterus and appendages; and in one, the cause was disease of the gall-bladder. In the pneumococcus peritonitis of children, there seemed to be a marked tendency for the exudation to be encapsulated. Operation should not be undertaken until the process had become localized. In adults, pneumococcus peritonitis was thought to be a great rarity. It is stated that pain, vomiting, and diarrhœa are the three constant symptoms in adults, and that fever is not observed except at the outset. Encapsulation of the exudate does not occur in adults. The presence of diarrhœa at the beginning would seem to point to the intestine as the starting point. The absence of fever is a striking point in differentiating this form from ordinary peritonitis.

Dr. John Hartwell thought that in some cases of pneumococcus peritonitis an infection of pneumococci through the diaphragm might explain the origin of the peritonitis. A certain number of cases of empyema had been reported in which the pneumococcus had been found, and yet there was no history of pneumonia, and no evidence at the time of operation of pneumonic consolidation. If it were possible for the pneumococci, to invade the pleura in this way, it seemed reasonable to suppose that it might, in like manner, reach the peritoneum. He had seen one case in which a septic peritonitis had developed four days after swallowing a fishbone. A very thorough search had been made at the autopsy for any perforation of the bowel, but none had been found, and the origin of the peritonitis could not be detected. The history was very clear, because the woman had come to the hospital at the time she had swallowed the bone; but as no urgent symptoms were present at the time, she had been told to return to the hospital if any new symptoms developed.

Dr. A. A. Berg spoke of the view that had been held, that peritonitis does not arise merely from the invasion of the peritoneum by bacteria, unless the latter are very numerous, or are unusually virulent. The speaker said he thought there was often a blood infection giving rise to toxins which destroy the normal absorbing power of the serous membranes. With regard to the cases in which the pus is encapsulated in various parts of the peritoneum, and cultures from this pus fail to show the presence of microorganisms, his belief was that these are not true cases of diffuse peritonitis, but rather examples of collateral exudation occurring in connection perhaps with a severe enteritis.

Dr. Martin W. Ware referred to a series of forty cases of ascites of young girls reported by French physicians. Nothing but turbid serum had been found in the peritoneal cavities, and cultures had failed to show the presence of microorganisms, although some of the cases had terminated fatally. These cases had been put down as idiopathic, but they should rather be looked upon as examples of defective bacteriological work.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 9, 1901.

EDWARD K. DUNHAM, M.D., PRESIDENT.

Demonstration of Points in the Technique of Frozen Sections.—Dr. F. C. WOOD made this demonstration. He said that he had found the preparation of frozen sections was made easier in very hot weather by first chilling the apparatus with the ether spray, and then spraying ethyl chloride upon the surface of the specimen. He also called attention to the value of a saturated solution of the French thionin as a nuclear stain for fresh tissues. The stain was as sharp as obtained with hæmatoxylin in hardened tissues. The thionin does not work in tissue hardened with formalin; the tissues must be fresh for use with it. This agent is also valuable as a means of demonstrating waxy degeneration, as the tissues stain blue, and the waxy portions a reddish purple. For rapid diagnosis it was quite important that the section should be held continuously in the forceps while passing through the various steps of preparation. If this were done, the preparation would not occupy more than a minute and a half to two minutes.

A Case of Glanders in the Human Subject.—Drs. WARREN COLEMAN and JAMES EWING reported this case. Dr. Coleman reported upon the clinical features as follows: The patient, J. E. D., thirty-six years of age, had worked as hostler and as a sort of veterinary surgeon, filing horses' teeth, etc. Three weeks before admission to hospital, he had been bitten on the third finger of the left hand by a horse said to have distemper. The wound had suppurated, and under treatment by a physician had healed after a week and a half. One week and a half before coming to hospital he had been taken ill with headache, disinclination to exertion, loss of appetite, vague muscular pains in the back and legs, and diarrhœa, and had grown progressively weaker. There had been no chill, epistaxis, cough, or pain. On physical examination he was found to be well nourished; face flushed and apathetic; eyes suffused and dull; pulse 88 and of good character; temperature, 104.6° F. The heart was normal in size, the sounds were fair and there were no murmurs. There were a few rose-colored spots over the abdomen, but there was no abdominal tenderness or distention. The liver and spleen were normal. The wound of the finger had completely healed. The next day, August 25, he was more apathetic, and at times slightly delirious. A tender, fluctuating swelling had developed in the middle of the outer and anterior aspect of the left leg, and the skin over it was red. The rose spots on the abdomen were more numerous, and some of them were very distinctly raised above the surface. On August 26 there was active delirium. The swelling on the leg being larger, it was incised, and six ounces of grayish, blood-streaked pus, which was deeply situated, was evacuated. It was noted that some of the rose spots had become popular, and that several small papules had developed on the forehead, face, chest, and back. A non-fluctuating swelling, about three inches in diameter, had appeared in the middle third of the left forearm. The leucocyte count was 13,000. On August 27 the swelling on the left arm had been incised, and about four ounces of thin, grayish saneous pus evacuated. A microscopical examination of this pus showed only cocci present. A few of the papules previously noted had become pustular, and fresh papules had appeared in the same localities. About this time the patient had begun to emaciate rapidly. By the next day he was decidedly weaker, and was delirious most of the time. Swellings had developed on the right forearm, the outer aspect of the left thigh, about three inches above the knee-joint, and on the outer aspect of the right leg, about the middle third. About this time a short, hacking, non-productive cough had developed. The Widal reaction was negative. On August 29 it was noted that some of the pustules had been ruptured by the manipulations of the nurse in attendance, and that they presented an umbilicated appearance. By the next day, these papules and pustules had become much more numerous. Numerous subcrepitant and mucous râles were heard over both lungs, and the breathing was roughened. The leucocyte count was 13,000. On August 31 there was a low, muttering delirium, and the eruption was more abundant. A smear from one of the pustules showed a few cocci, and fewer bacilli presenting the appearance morphologically of the bacillus mallei. Cultures were taken from the pustules, and 5 c.c. of blood, taken from a vein at the bend of the elbow for bacteriological examination, afterward gave a pure culture of the bacillus mallei. The patient died on the morning of September 1.

Commenting upon the case, Dr. Coleman said that the abscesses were remarkably symmetrical, all of them deeply situated, and, for the most part, without signs of inflammation in the overlying skin. The abscess cavities had no pyogenic membrane. The abscesses were intramuscular, and the pus dissected the muscles out along their sheaths for variable distances. The abscess in the lower part of the left thigh had burrowed nearly to the knee-joint. Practically no reaction had taken place in the incisions, and the cavities had remained nearly dry. Down through the incisions the muscles looked like those of a cadaver. The eruption had first appeared as macules over the anterior abdominal wall, presenting much the appearance of the rose spots of typhoid. That some of them disappeared was shown by the marks placed around them with an indelible pencil, but by far the majority developed into papules and subsequently into pustules. The eruption came out slowly at first; then with great suddenness innumerable papules and pustules appeared on the forehead, face, chest, and upper part of the abdomen. There were also scattered lesions on the scalp, back, and extremities. During the first part of the illness the change from macule to papule and pustule proceeded slowly, occupying two or three days, but later the transition was measured by hours. The individual lesions were situated on a hyperæmic base, which, strangely enough, became anæmic after death. According to G. S. Woodhead, in Allbutt's practice, the base is anæmic sometimes during life. The nasal mucous membrane gave no evidence of involvement. The cough was due to lesions of the trachea and bronchi, to be described by Dr. Ewing. None of the accessible lymph nodes were involved. From the length of the incubation period it seemed probable that the man was not infected with glanders at the time the horse bit him. Woodhead states that the incubation is very short after inoculation, within twenty-four hours, unless the inoculation takes place through an old wound or through no apparent wound, when it may be prolonged to one or two weeks, or more. Moreover, in the former case, lymphatic involvement is prominent. Glanders in the human subject was formerly much more frequent, the older journals containing records of many cases. The present case is the fourth, according to the records of the Health Department, that had occurred in New York City since 1888, viz., one in 1888, one in 1893, one in 1899. The temperature range had been high, only once falling below 103° F., and the highest point being 105.6°. Until within two days of death the pulse rate had been remarkably low, considering the temperature, having varied from 78° to 100°.

Dr. JAMES EWING presented the pathological report on the case. The autopsy was made on September 2, thirty hours after death. The skin showed about one thousand papules, macules, or pustules, irregularly distributed over the body, varying in size from a pinhead to 1 cm. in diameter. They were generally acuminate, sometimes slightly umbilicated, while the largest lesions were ulcerated and excavated. Many of them resembled variolous pustules, but were more distinctly purulent and not markedly umbilicated. They were usually surrounded by a peculiar anæmic halo, 1 to 2 cm. in diameter. In

some areas the lesions were confluent, and the skin and subcutaneous tissue was indurated and discolored by hemorrhage. A few of the same pustular lesions were found in the respiratory musosa. The skeleton muscles were the seat of perhaps a score of abscesses, ½ to 3 cm. in diameter, containing thick blood-stained pus. The heart was normal. Both lungs exhibited numerous consolidated areas, ¼ to ½ cm. in diameter, single or conglomerated, resembling tuberculous foci. These areas were very light colored, and were very sharply marked off from the surrounding pulmonary tissue, which was markedly hyperæmic. These nodules projected slightly on section, and on the pleural surface. They were quite firm. The upper portion of the left lung was diffusely consolidated. The pleura was irregularly coated with fibrin. The bronchial mucosa was hyperæmic, very slightly coated with mucus, and exhibited a few well-raised pustules. The bronchial nodes were all hyperæmic; two of them were softened, and one of these two had ulcerated into the left bronchus, producing a large ragged ulcer of the mucosa. The pneumonic area in the left lung had resulted from the inspiration of the contents of the softened node. No other lymph nodes in the body were found to contain specific lesions. Those in the groin, axillæ and along the left arm were not enlarged on palpation, but were not dissected out. The spleen was the seat of a well-marked acute hyperplastic splenitis. There was acute degeneration of the liver and kidneys. The testicle and bladder were normal. The gastro-intestinal tract showed slight catarrhal inflammation, and Peyer's patches were atrophic. Over the right external occipital protuberance was a subperiosteal collection of thick, coherent pus, and between the dura and skull a similar collection. The meninges were hyperæmic and œdematous, but the brain was normal. The bone marrow in the ribs was cellular and hyperæmic. Microscopical examination of the inflamed tissues in both the human subject and in the guinea-pig demonstrated the usual peculiar lesions of glanders. The main features of these lesions appeared to be the following: (1) An acute exudative process, the exudate being composed chiefly of leucocytes, among which the polynuclear cells were slightly in excess of the mononuclear; (2) A peculiar necrotic process affecting the exudate and the tissue involved. Karyorrhexis of nuclei and hydropic and fatty degeneration of the cell bodies appeared to be the exclusive type of necrotic process induced. The wide areas of complete coagulation necrosis seen in tuberculous foci of equally rapid formation were missing. Giant cells were not observed; (3) A striking feature, especially in the muscles, was the very sharp line of demarkation between the necrotic process and normal tissue. No evidence of a productive process could be discovered

The bacteriological study of the case had consisted in the examination of smears of the exudate from various lesions, cultures from these lesions, and from the blood, and the inoculation of a guinea-pig with the material. On August 31, slightly less than twenty-four hours before death, Dr. Coleman had drawn about 5 c.c. of blood from the median basilic vein and had distributed it in two tubes of ordinary broth. These had been kept on ice until September 2, and had then been placed in the thermostat. On September 3 there had been no growth, but on the following day an abundant flocculent growth had appeared, resembling that of the streptococcus pyogenes. It was flocculent, occasionally adherent to the sides of the tube, leaving the fluid clear. These proved to be, morphologically, bacillus mallei in pure culture. From the post-mortem, Blood colonies of the glanders bacillus and of various unidentified cocci had developed on blood serum. Pus from the intramuscular abscesses had given the glanders bacillus and the staphylococcus pyogenes aureus. The lung had yielded an abundant growth of bacillus mallei and of a large filiform bacillus. From a pustule of the skin previously peeled off with 5-per-cent. formalin and sterile water, a growth was obtained of the glanders bacillus and of a large unidentified coccus. Smears of the skin lesions showed only the glanders bacilli without cocci; from the pus of the abscess, glanders bacilli and staphylococci were obtained, while from the lung only glanders bacilli developed, but in great abundance. The earliest identification of the glanders bacillus had been obtained in a diffuse, slightly brownish growth at first in pure culture, but later overgrown by a large filiform bacillus from the lung on potato. This growth had appeared in less than twenty-four hours. On September 3, a male guinea-pig had been inoculated intraperitoneally with an emulsion of the lung tissue. The pig had not appeared much affected until September 8, but it had died the following day. The autopsy showed a few small collections of thick pus in the skin and muscles at the site of puncture. The parietal peritoneum was granular, the visceral shiny. There was no ascites. There was one large pustule projecting prominently from the peritoneal surface of the small intestine. Peyer's patches were inflamed and swollen. The lungs and kidneys were negative. The Malpighian bodies of the spleen were prominent. The liver showed numerous small whitish foci. The testicles were much swollen, both measuring 4 cm. across. The tunica vaginalis was thickly infiltrated with the typical whitish foci of glanders. On section, these foci were found to be limited to the tunica, and microscopically they exhibited the usual necrotic lesions of glanders. The cultures taken from the heart's blood were sterile. On broth, cultures from the testicles gave staphylococcus aureus; on blood serum the bacillus of glanders,

Dr. W. H. Park said he thought he had seen the case reported by the Health Department as having glanders in 1899. The man was between sixty and seventy years of age, in poor condition, and he had a series of small abscesses on one of his legs. These measured one to one and a half inches. Some of them had opened, and all of the abscesses were sluggish. He had taken the pus from two with a hypodermic needle, and had scraped out two or three of these abscesses. From none of these had he obtained the glanders bacillus, and inoculations into guinea-pigs had proved negative. It seemed to him that the case was not really one of glanders.

Dr. A. J. Lartigau asked Dr. Ewing if he had succeeded in staining the bacilli in sections, and if so by what method. He had personally found the methods recommended rather unsatisfactory because of the rapid decolorization of the organisms.

Dr. Ewing said that he had made some attempts to stain the glanders bacillus in the tissues, and had succeeded only very imperfectly. The intramuscular abscesses had given the best results. For ordinary purposes he had succeeded in getting with methylene blue some results, but they were far from satisfactory. He had not tried Loeffler's alkaline methylene blue. Early in the summer, he had been asked to examine the mucus from two or three horses on Long Island. One of the animals had died from what the Board of Health called glanders, and the other horses had contracted the disease from the first horse. The diagnosis was in dispute. Numerous cultures of the mucus had been made on various media, but they had failed to show any glanders bacilli. Then, some of the mucus scraped from the nostrils had been examined. In smears of this material he had found a few bacilli, but nothing even suspicious of glanders. All the plates had been negative. He had inoculated two guinea-pigs with an emulsion of this mucus and crushed tissue. One of them had died within two weeks of a slow septicæmia, and no lesions were found in the body. The other pig had survived and had presented no symptoms. The horses had gone on, two of them dying naturally and one being shot by the health authorities. None of them had developed farcy-buds, though the health officers and the veterinarians in the vicinity were agreed that the

disease was glanders. From conversation he had been led to believe that glanders was rather common. If this were so, there should certainly be more cases in the human subject, and he was of the opinion that certain cases of cutaneous and muscular pyæmia belonged in this category, but were differently diagnosed. Mallein had been injected into the horses in several instances, and in each instance there had been a rise of temperature; but for various reasons the reaction had not been regarded as satisfactory. The experiment had also been tried, at his suggestion, of injecting small doses of mallein as a curative agent. This had also yielded negative results.

A Case of Idiopathic Acute Diffuse Phlegmonous Gastritis.—Dr. OTTO H. SCHULTZE presented a stomach with markedly thickened wall. With this exception, the stomach was normal in size and form, its peritoneal coat was smooth and glistening, its contents a small amount of bile-stained mucus, and its weight nineteen ounces. The mucosa was bile-stained; no solution of continuity could be found. On section, clear serum had flowed freely from the cut surface on the slightest pressure. The wall was thickened throughout, measuring 1 cm., the increase being chiefly in the submucosa, but also in the muscularis, the former being equal to, or greater than, the other layers combined. The process extended into the first portion of the duodenum, and the cardiac end of the œsophagus.

Sections from the pyloric and cardiac regions, and winding between them, stained with hæmatein and eosin and by Van Gieson's and Weigert's methods, were presented.

The mucosa showed the changes of chronic catarrhal gastritis, namely, increase in the stroma with infiltration of lymphocytes, not sufficient in extent, however, to have caused any marked atrophy of the tubules. At very infrequent intervals the stroma adjoining the muscularis mucosæ showed evidences of œdema in microscopic areas.

The muscularis mucosæ was normal.

The submucosa was the seat of marked œdema, the meshes of the fibrous tissue being distended with amorphous and granular matter which remained sustained in the Weigert sections. Adjoining the muscularis, infiltration with polynuclear leucocytes became evident.

The fibers of the muscularis were separated from one another in larger and smaller groups, even to individual cells, by an infiltration of polynuclear leucocytes, most extensively in the portion adjoining the submucosa, less so toward the peritoneum, which this infiltration reached in places, but did not invade.

The mesothelial lining of the peritoneum was not preserved in the sections. The connective-tissue layer showed no evidence of reaction.

Streptococci in short chains were found throughout the submucosa and muscularis; none were found in the mucosa. Cultures were not made.

The lesion was considered idiopathic, since no other focus of infection was found, nor could the evidences of injury, namely, contusions of the cheek and temple of no great effect, and simple fractures of the left fifth, sixth, and seventh ribs, be considered of etiological importance. The other lesions were, subacute meningoencephalitis of the type usually found in cases of dementia paralytica, chronic interstitial nephritis, chronic interstitial pancreatitis, chronic perisplenitis, and slight brown pigmentation of the heart muscle, although not without effect, could not compare in importance as a cause of death with the extensive stomach lesion.

Numerous sections from the peritoneum, besides that of the stomach, were examined. With the exception of the old perisplenitis mentioned, they showed no evidence of peritonitis. The case had been made the subject of a coroner's inquest, since the coroner's physician had ascribed death to traumatic peritonitis—a diagnosis which he failed to substantiate at the inquest.

The clinical history of the case, on account of unfavorable circumstances, showed little of diagnostic value. The deceased, a male, forty-one years of age, of spare physique, a native of Austria, by occupation a truck driver, was admitted to the insane pavilion of Bellevue Hospital on June 13, 1901. On that morning he had entered a strange apartment, thinking it was his home, and became so violent that he had to be forcibly restrained, and finally taken by the police to Bellevue Hospital. On admission his temperature was 99.4° F., pulse 76, respiration 22. He was excited, noisy, and so violent that during much of the time restraint was found necessary. His appetite was good until June 16, when, after having eaten his dinner, he vomited and refused his supper. Vomiting of bile continued during the 17th; he was restless, excited, seemed weaker, especially during the night, and was apparently in pain, since he rubbed his abdomen with his hands. There was no tympanitis. Death took place at 5.30 A.M., June 18.

His medication consisted of hyocine, atropine, and morphine during his violent periods; strychnine and whiskey when weakness set in.

An autopsy, admittedly incomplete, since larynx, heart, and brain were the only organs incised, was performed by the coroner's physician on June 18. The second autopsy was made 2.30 P.M., June 19, the body having been kept in cold storage during the interval.

Dr. L. A. CONNER referred to a case at the New York Hospital during the past year. Here, too, there had been a diffuse phlegmonous gastritis with the same violent gastric symptoms for a few days, and with the same obscure etiology.

Results of Feeding and Inoculating Calves with Tuberculous Material from Human Subjects.—Dr. W. H. PARK presented a report on these experiments. Five calves, weighing about 150 pounds, had been taken and tuberculin injected into them. Four had been taken for feeding experiments and one reserved as a control. The feeding had been done entirely with sterilized milk so as to exclude any possibility of bovine tuberculosis being transmitted by the milk. The sputum from tuberculous patients at St. Luke's Hospital had been collected for two weeks, and the calves had received a quantity of this sputum in their milk, and also some of the bacilli from the sputum were injected. Four days ago they had been inoculated with tuberculin, and three out of the four had reacted, one slightly. The autopsy on one calf showed nothing but enlargement of some of the lymph nodes. Smears from these nodes showed no tubercle bacilli. Therefore, after two months and a half, this calf showed no lesions of tuberculosis except enlargement of some of the lymph nodes, and no tubercle bacilli were found in these glands. However, they had reacted to tuberculin. The other three calves had gained in weight just about as much as the control calf.

Dr. E. L. DOWES suggested that some of the calves be subjected to inhalation experiments.

Dr. PARK replied that such a method would be very troublesome, and as tuberculosis in calves is more apt to be of the glandular type, there was not the same interest in experiments on introducing tuberculous matter by way of the lungs

---

Injection of Quinine.—Professor G. Bacelli, head of the Medical Clinic at Rome, and Minister of Agriculture in Italy, recommends the intravenous injection of quinine for malignant ague. Professor Bacelli, speaking at Novara, a short time ago, stated that, in accordance with his suggestions, some Italian veterinarians had treated foot and mouth disease by intravenous injections of corrosive sublimate. The results had been most gratifying, and far surpassed those of any other methods

MANHATTAN DERMATOLOGICAL SOCIETY.

A Regular Meeting Was Held on Friday Evening, November 1, 1901, at the Residence of Dr. R. Abrahams, 156 Clinton Street.

Dr. GOTTHEIL PRESIDED.

Acute Generalized Seborrhœal Eczema.—Dr. R. ABRAHAMS presented a child of eight weeks, with a generalized macular and diffuse lesion. There were cough and snuffles, but the palms and soles were free.

Dr. SOBEL considered the lesions too highly inflammatory for syphilis; all the stigmata of a congenital syphilide were absent.

Dr. OBERNDORFER stated that the freedom of the palms and soles and the absence of fissures are significant.

Dr. BLEIMAN thought that the case required careful watching.

Dr. GOTTHEIL remarked that the presence of macular lesions was unusual.

Chronic Papular Urticaria.—Dr. J. SOBEL presented a child of two and a half years who for a year and a half has had a papular eruption of the face, arms, buttocks, thighs, and legs. Itching was intense, scratch marks were evident, the inguinal glands were enlarged, and some papules had become pustular on account of infection by scratching. Such cases are often diagnosed as prurigo iritis. The interdigital regions were free and scabies was excluded.

Dr. BLEIMAN thought that scabies and prurigo could be excluded. Chronic papular urticaria is the condition present.

Dr. L. WEISS believed that such cases were better termed strophulus infantilis. (Blaschks.) This condition begins in early childhood, is obstinate and persistent, and is often the forerunner of prurigo.

Dr. GOTTHEIL does not think that scabies can be ruled out.

Dr. R. ABRAHAMS considered it chronic papular urticaria. Pilocarpine in daily doses of gr. $\frac{1}{12}$–$\frac{1}{10}$ is highly recommended.

Prurigo.—Dr. BLEIMAN presented a boy of eleven years who from his second year has had a hard papular eruption on the face and exterior surfaces. This had been persistent, with periods of remissions, never disappearing entirely. Improvement occurred during the warm months. Prurigo buboes were absent. Dr. Geyser thinks that the condition may be the remains of a prurigo.

Dr. J. SOBEL believed that on account of active treatment a positive diagnosis cannot be made. He should want to see much more of the lesions before venturing a positive diagnosis of prurigo.

Dr. OBERNDORFER considered it a chronic papular eczema. He has had similar cases lasting as long as twelve years.

Dr. L. WEISS stated that this is positively prurigo. The existence of the eruption since infancy, the involvement of the extensors, and the infiltration of the skin speak for it. The absence of buboes does not mitigate against the diagnosis.

Dr R. ABRAHAMS stated that the case does not correspond to his conception of prurigo. In nine years typical lesions ought to exist all over the body. He would call it chronic eczema.

Dr. GOTTHEIL did not see why any characteristic lesions ought to exist all over the body. He would call it chronic eczema.

Dr GOTTHEIL further did not see any characteristic lesions of prurigo. He has seen the patient when the flexors were involved, and looks upon it as a chronic eczema.

Rhinoscleroma.—Dr. GOTTHEIL showed a woman of sixty-four, with involvement of the nose and lip. The ala nasi have the hard, cartilaginous, ivory hardness so characteristic of the condition. The hard palate is also attacked. Despite the books, ulceration occurs as in this case. Recently, a cure has been reported from treatment with antitoxin from the bacillus of rhinoscleroma.

Dr. GEYSER remarked that radiotherapy would only hasten the end of the patient.

Dr. J. SOBEL had previously observed this case in the service of Dr. C. W. Allen. With him he had seen a second case in which the lesion involved the post-nasal space and larynx, necessitating a tracheotomy. Ulceration may certainly occur. Rhinoscleroma may involve the tonsil primarily, and render differentiation from chancre and cancer necessary.

Dr. L. WEISS stated that ulceration may take place when the vitality of the tissue is encroached upon by pressure.

Keratosis Follicularis.—Dr. L. WEISS presented a man with lesions of both forearms.

Mollusca Contagiosa of the Penis.—Dr. J. OBERNDORFER showed a young man with multiple lesions limited to the penis. The location was interesting and rare.

Dr. J. SOBEL stated that the situation was uncommon. In children the lesions often became infected, producing pustules. The condition is both auto- and hetero-inoculable.

Dr. BLEIMAN has seen similar cases in children in combination with involvement of other parts, face, chin, and body.

Dr. L. WEISS stated that, as a rule, other parts of the body are affected.

Dr. ABRAHAMS has seen many family cases.

Dr. GOTTHEIL observed one case in which multiple mollusca occurred on the penis and scrotum.

Atrophia Cutis Propria.—Dr. R. ABRAHAMS presented a man of fifty-seven, in whom forty years ago eczematous lesions appeared in the popliteal space. Later, similar lesions appeared at the ankles. This was followed by atrophy, varicose veins, and ulcerations at the ankles.

Dr. J. SOBEL said that his first impression was scleroderma. He looks upon it as an atrophy due to trophoneurosis.

Dr. OBERNDORFER first thought of scleroderma. It is, however, a clear case of atrophia cutis propria, with atrophy, varicose veins, and ulceration. The varicose veins do not bear any relation to the atrophy, because otherwise atrophy would be more common.

Dr GOTTHEIL has seen but one similar case. The erythema at the edges points toward an inflammatory condition.

Dr. GOTTHEIL showed photographs of cellulitis of the lip, secondary sarcoma cutis, generalized lichen planus, lichenification in old eczema, erythrasma of the buttocks, dysidrosis, and erythema multiforme.

Rarefying Osteitis Simulating Atrophic Rhinitis.—From a series of cases, E. E. Musson concludes that the differential diagnosis of atrophic rhinitis and sinus suppuration complicated with rarefying osteitis is a difficult one. In atrophic rhinitis the process of resorption of the tissues is a more extensive and more generalized one and the mucosa is thinned out, closely outlining the formation of the nasal cavities. It is smooth and of a dirty gray color, while in purulent sinus disease it has a congested and granular surface. In sinus disease the probe will reveal carious bone, in atrophic rhinitis only smooth mucosa. Crusting is more common in the latter, but localized in the former in the superior and middle meatus. In the latter the olfactory twigs are always eventually destroyed, not necessarily in the former. The atrophic membrane does not tolerate surgical procedures, while in osteitis removal of carious bone with the opening up and drainage of the sinuses improves the ozena.—*Proceedings of the Philadelphia Medical County Society.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 23, 1901:

	Cases.	Deaths
Measles	316	11
Diphtheria and croup	269	40
Scarlet fever	184	12
Smallpox	6	1
Chickenpox	34	..
Tuberculosis	241	131
Typhoid fever	75	16
Cerebrospinal meningitis	..	3

Transmission of Scarlet Fever to the Cat.—At the present time, when the tendency of a large number of scientific men is to discourage the belief that disease can be transmitted directly from animals to man and vice versa, the account given by Dr. Rapin in *Le Progrès Médical*, May 4, of scarlet fever being communicated from children to cats, possesses exceptional interest. Dr. Rapin gives an account of two instances in which he believes cats were attacked by the disease. The first instance occurred in 1894. A small white cat, quite young, was the constant companion of two little girls who were suffering from scarlet fever. This kitten soon became ill, and continually uttered little plaintive cries. Its body was hot, skin rosy, and tongue bright red in color. This was followed by a mealy desquamation of the skin, and falling out of the hair, most pronounced at first in the posterior part of the body. The second instance was observed in February, 1900, in a cat three weeks old, belonging to a little girl, who had an attack of scarlet fever. It also suffered from a febrile illness, followed by falling out of the fur, and branny powdering all over the body. In both instances, the cat was very young, and to this circumstance, Dr. Rapin attributes a great deal of importance, his view being that the susceptibility of the cat to the disease becomes gradually less with age, and gradually wholly disappears.

The Position of the Medical Profession in Austria.—The Vienna *Free Press* says: "The number of unemployed or scarcely employed doctors is shocking, especially in the larger cities, and this does not apply alone to the younger men. In vain do they struggle to make a decent living. They look with envy up to their professional brothers, who, in spite of the best qualifications, the finest training, in spite of "good luck," are only able to make enough to support their families in a very modest manner, and are unable to provide for their old age and the future of their family. The medical profession is the victim of so-called humanitarian legislation, especially of the law of 1888, founding companies insuring working men against illness. It is not an overcrowded condition of the profession which is to blame; for Vienna, a city of 1,500,000 inhabitants, has scarcely more than 2,000 doctors, and several hundreds of these are army and hospital doctors, hence who are scarcely a factor in the general practice. Neither is it the retrogression of the so-called "middle class," the members of which summon a physician not less often than formerly, and pay him not much less, but it is the abstraction of the most numerous classes of the population through the Kranken Kasse (insurance company) law which accounts for the degeneration in medical practice.

Ringworm in Schools.—An important question in London, says Dr. P. Abraham, is the prevalence of ringworm in schools. The majority of the subjects of the condition who come under my notice have contracted their ringworms in the board schools. I think the time has come to do something in the matter. It is not fair that poor people should be forced, as they are, to send their healthy children to institutions where there is every probability of those little ones contracting such diseases. Under the present system, infected children may, and often do, attend school for weeks or months, and spread ringworm, pediculosis, etc., unchecked. The obvious remedies are that in the first place, every school be periodically inspected by a skilled medical observer, and secondly, that all cases of ringworm be isolated from healthy children, and taught in separate rooms from the others, or, better still, in distinct and special schools. Mr Malcolm Morris, speaking on the same subject, a short time ago, urged that special schools should be established for children suffering from contagious affections of this nature.

Yaws and Syphilis.—The question of the identity of the disease known as "yaws" with syphilis, says Mr. Jonathan Hutchinson, has been illustrated by two remarkable cases. In one of them a man presented himself, who had contracted yaws from a primary sore on his forearm while in West Africa. He had passed through the ordinary secondary eruption, which had been recognized as yaws by several good authorities on the spot. He came to us eight months from the onset still covered with a polymorphous eruption on his limbs, and with peeling patches in palms and soles. No one who saw him doubted that he was now suffering from syphilis, and when subsequently he was presented at a meeting of the Tropical Society, British Medical Association, a unanimous vote to this effect was taken. Portraits have been preserved in the museum and with them those of another exactly parallel case.

Counsel to Smokers.—The Royal Academy of Belgium gives the following advice to smokers:

"Do not use moist tobacco, since nicotine then escapes with the vapor and is not decomposed.

"Do not smoke either while fasting or a short time before meals.

"When smoking cigars or cigarettes always use an amber, meerschaum, horn, or cherry holder.

"Nicotine vaporizes at 250 degrees, and the portion of it which is not decomposed in the center is attracted toward the tip, and accumulates there; it is, therefore, prudent to throw away the last quarter of a cigar.

"Do not smoke a pipe which has a short stem.

"Of all methods of smoking, the cigarette is the least offensive."

Quinine Administration in India.—The Sanitary Commissioner's report shows that some progress is being made in the Northwest Provinces and Oudh toward Professor Koch's ideal, the quininizing of the population. A scheme for the sale of quinine, through landlords and their agents, was introduced in the districts of the Allahabad, Rohilkhand, Lucknow, and Fyzabad Divisions; but as a beginning was made only in October last, it is too early to predict whether the non-official agency will prove successful. The government of Madras has recently offered to reduce the price paid for quinine in bulk, and we are told that it will be possible, when the arrangements have been completed, to reduce the sale price of quinine packets by one-third. An increased sale of the drug may then be expected.—*Journal of Tropical Medicine*.

Shop Hours in Great Britain.—The report of the select Committee of the House of Lords on early closing of shops was issued recently. The committee state that the evidence taken has convinced them that earlier closing would be an immense boon to the shop-keeping community, to shop keepers and shop assistants alike; that the present hours are grievously injurious to health, especially in the case of women, and under these circumstances, the committee recommend that the town councils should be authorized to pass provisional orders making such regulations in respect to the closing of shops as may seem

to the ... be necessary to act under their jurisdiction these provisional orders to be submitted to Parliament in the usual manner before acquiring the force of law. The committee add that special enactments for restraining the outlay involved and providing for its discharge may be necessary.

The Treatment of Gastric Ulcer.—Robin bases his treatment on four fundamental indications, viz., prophylaxis, functional rest, treatment of secondary symptoms, and relief of complications. Formerly, the milk treatment was commenced immediately the existence of gastric ulcer was recognized; but the author's experience has shown him the necessity of subjecting the patients to a preparatory treatment consisting in absolute rest, before putting them on a milk diet. The following is the treatment adopted to fulfil this indication: The patient is kept in bed; a towel stupid in hot water and covered with oiled silk and cotton wool is placed over the epigastrium, and kept in position by means of a flannel bandage; no nourishment is given by the mouth, not even milk or water. Each day the patient is given four enemata composed of two eggs beaten up with two spoonfuls of peptone, thirty grains of salt, a few drops of laudanum, and three ounces of glucose (20 per cent.). The whole enema should measure about six fluid ounces. Two other enemata of simple warm water are given during the day to supply the organism with the necessary amount of liquid. To accustom the patients to this treatment, it is well to increase the number of enemata gradually until complete tolerance is obtained. When intolerance is present (which happens in about one of every fifteen cases according to Robin's experience), we must endeavor to overcome it by increasing the laudanum to twelve or fifteen drops, or by suppressing the salt and the peptone, which seem to be the substances that usually provoke intolerance. In the majority of cases, the symptoms are appeased, the gastric pain and the epigastric tenderness disappear, and the loss of weight is checked. The rest cure having come to an end, the patient should be put on a milk diet, gradually increasing the daily amount up to four quarts. This *régime* should be continued not less than six months. At the expiration of this period, a mixed diet may be ordered for a fortnight, consisting of milk foods prepared with tapioca, arrowroot, rice, etc., and a few vegetables. After this period of transition the milk is suppressed, and meat and fish ordered, as well as eggs, vegetables, and cooked fruit.—*Medical Record and Medical Chronicle.*

A Position to Aid in Surgery About the Diaphragm. G. Kelling says that difficulty is frequently experienced in gaining access to the abdominal regions in the neighborhood of the diaphragm, and describes a change of position that he has found useful. The patient is slid down the table till his pelvis is free and hangs vertically down over the edge, while the trunk is still horizontal and held in place by straps crossing the thorax. The median laparotomy incision is enlarged by a transverse cut to the tip of the twelfth rib, when it will be found that the whole abdomen opens up, and the intestines must be held in place by an assistant to keep them from falling out of the wound. The anæsthetizer and the patient's head should be shut off from the wound by a sterile screen.—*Centralblatt für Chirurgie.*

Treatment in Inebriety. The question of treatment in inebriety must be determined largely from the physical conditions which enter into the problem, of which age, constitution, physical and mental vigor, temperament, occupation, previous habits, and purposes and ambitions in life are the prominent factors from which to draw conclusions. Often associated with this are physical states, such as failures and successes in life, the element of hope, and faith, or the disappointments which have influenced and changed the current of events, previous treatments, in asylums or at home, and their success and failure, also use of other drugs, together with worriment, mental care, and anxiety.—*Journal of Inebriety.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended Nov. 23, 1901:

		Cases	Deaths
States—United States.

SOME OBSERVATIONS ON THE BORDERLAND BETWEEN MEDICINE AND SURGERY.*

By GEORGE WOOLSEY M.D.,
NEW YORK.

SURGEON TO BELLEVUE HOSPITAL, ASSOCIATE SURGEON TO THE PRESBYTERIAN HOSPITAL, PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF CORNELL UNIVERSITY.

MR. PRESIDENT AND MEMBERS OF THE WESTCHESTER COUNTY MEDICAL SOCIETY:

I wish, in the first place, to thank you for the honor you have conferred upon me in inviting me to read a paper before this society, and in the second place to say that in choosing my subject, I felt that the majority of you would be more interested and edified with some remarks upon the topic chosen than if I had selected a technical surgical subject With the improvement of our art and practice, an increasing number of conditions which were formerly treated symptomatically have been subjected with more and more success to operative treatment. Thus the frontier or borderland between medicine and surgery has been a changing one.

To bring together expressions of opinion of physicians and surgeons on topics more or less definitely within this borderland, a journal is published in Germany called *Mittheilungen aus den Grenzgebieten der Medicin und Chirurgie.* I merely instance this fact to show the interest that is rightly taken by both physicians and surgeons in pathological conditions that concern both. The number of such conditions is so great that I shall confine myself to the more common, and hence more important, ones, merely mentioning some of the others which are engaging the interest of both branches of the profession.

One of the commoner conditions that interest both the physician and the surgeon is carcinoma of the stomach. Patients afflicted with this malady almost always are first seen by the physician, while to the surgeon falls the operative treatment, either palliative or radical. It is the most common form of malignant disease, constituting from 21.4 per cent. (Welch) to 41.5 per cent (Haberlin) of all forms of malignant neoplasms. Hence its great importance from a practical standpoint. As surgery offers the only hope of cure, it should properly be considered a surgical disease, yet as its diagnosis usually falls to the physician, it is one of those diseases that belong to the "borderland." This very question of diagnosis is of the greatest importance, for upon an early diagnosis and an early operation depends the success, and even the possibility, of any radical treatment. Pain in the stomach, loss of appetite and flesh, digestive disturbances, vomiting, etc., the presence of a tumor and chemical or bacteriological changes in the stomach contents are among the most important diagnostic symptoms. Many of these, however, are of no value for an early diagnosis, which should be the first objective. Thus a tumor gradually becomes discernible in somewhat over two-thirds of the cases, yet, according to Czerny and many others, a radical operation is out of the question by the time a tumor can be felt. Although the absence of free hydrochloric acid occurs in 60 per cent. of cases, yet it is not always found at an early stage of the disease, and in those cases of carcinoma developing upon ulcer, the hydrochloric acid may even be increased. Lactic acid, together with the Oppler-Boas bacillus, is present late in the course of the disease, for they occur only after impaired motility, absence of hydrochloric acid, and reduction of albumen digestion have been developed. The reduced motor power of the stomach, with or without obstruction, is a constant symptom, but is common to non-malignant diseases. A positive diagnostic indication is furnished by the finding of cancer elements in the fragments washed from the stomach, but they are rarely detached spontaneously in the early stages. Hence systematic attempts have been made by Hemmeter and in Boas' laboratory to detach such fragments of the growth for diagnostic purposes. Apart from the chance of obtaining a small fragment of the new growth in the stomach washings early in the course of the disease, we find that the most characteristic symptoms, those on which a positive diagnosis depends, are only developed late in the course of the disease. The importance of an early diagnosis is nevertheless all-important to the surgeon, in order that a radical operation may be undertaken. As Mayo[1] well says: "The surgeon should not ask the physician for a diagnosis of gastric cancer; if we wait for that, we are pretty sure of being too late. It is the suspicious cases which should be explored, and it is the duty of the physician to urge this when in doubt. "The exploratory incision for suspected cancer of the stomach, instead of being a last resource, should be one of the first, and promptly undertaken if the condition cannot be proved to be non-malignant." Given a person of middle or advanced age, of previously good digestive powers, or, possibly, with a previous history of ulcer of the stomach, who begins to complain of epigastric pain, loss of appetite, and considerable and continuous loss of flesh, the physician should lay the matter before the patient and call in the surgeon to confirm the diagnosis by an exploratory operation, unless a fragment can be obtained in stomach washings. In this way, and in this way only, at the present time, can a positive diagnosis be made at such an early date that a radical operation may be undertaken with a fair chance of success. There is no reason, except the difficulties of the diagnosis, why the radical cure of cancer of the stomach should not approach in its success that of cancer of the breast or uterus.

This radical operation, if undertaken early, before the disease is extensive and the patient's strength is seriously undermined, is a comparatively safe operation and offers a fair chance of permanent cure. The Kocher operation for pylorectomy and

*Read before the Westchester County Medical Society.

[1] *Annals of Surgery*, August, 1900, p. 251.

partial gastrectomy is suitable to those cases in which the new growth is situated at the pyloric end of the stomach, which comprise at least 60 per cent. of all cases. Maydl's cases showed a mortality of only 16 per cent. and a most encouraging percentage of permanent cures, 50 per cent. being still alive at the time of his report. In the Kocher operation, the pyloric end of the stomach is removed, wide of the new growth; the opening made is completely closed, and the duodenum is anastomosed by a Murphy button, with the antero-inferior stomach wall. If extensive adhesions exist within the surrounding structures, the radical operation is contraindicated, unless the case is otherwise favorable; for the adhesions increase the difficulties and dangers of the operation, and direct extension of the malignant infiltration is likely to occur along them. Fortunately, lymphatic infection is a late phenomenon and comparatively rare in gastric carcinoma. Sutton says that in only about half the cases (a rather low estimate) dying of gastric cancer are glandular involvements found, and among twenty-eight recurrences after extirpation, only one involved the glands. These facts are encouraging for the radical operation when practised early. When the radical operation is contraindicated by the condition of the new growth or of the patient, we can still, of course, resort to the palliative gastroenterostomy. In suitable cases, it relieves pain, promotes comfort, and prolongs life. The relief from the irritation of the passage of food over the new growth decidedly delays the progress of the disease, as colostomy does in rectal cancer. The cases suitable for gastroenterostomy are those in which there is, or is likely to be, obstruction at the outlet of the stomach from the presence of the new growth. This is likely to occur in the 60 per cent. of cases in which the tumor is situated at the pyloric end of the stomach. Obstruction of the cardia by the new growth, occurring in 10 per cent. of cases, demands gastrostomy at an early date.

Although the palliative operations relieve pain, promote comfort, and prolong life, so that the patient may gain flesh and strength, and even return to work and live eighteen months, or longer, it is, at best, a palliative operation. The radical operation is what we must aim at in the future. This implies early operation, depends upon early diagnosis, and demands the intelligent co-operation of physicians and surgeons.

But it is not alone in malignant disease of the stomach that this co-operation is demanded. Surgery affords the best treatment in many other conditions of the stomach, and on account of their non-malignant character, this treatment is radical and permanent.

In perforating ulcer of the stomach, no treatment but operation is of avail, and the earlier the diagnosis and the operation the better the prognosis. Fuirey[1] shows a mortality of 48 per cent. in the 268 cases so far reported, and of 38 per cent. in the twenty-one most recent cases. As perforation occurs in only 6.5 to 18 per cent. of all cases, surgical interference on this account is not particularly common in ulcer of the stomach. But there are other indications for surgical interference in gastric ulcer, such as repeated or excessive hemorrhage and intractable pain resisting all medical treatment. In the latter case, gastroenterostomy gives relief, but not as promptly as in cancer of the stomach.

It is in cases of benign obstruction of the pylorus that surgical treatment has achieved the greatest success. Whether due to a cicatricial contraction of the pylorus following a gastric ulcer or to a hypertrophic stenosis following chronic dyspepsia, often with hyperacidity, the stomach becomes dilated and there are stasis and decomposition of its contents, which condition irritates the stomach and causes hypersecretion and hyperacidity. This hyperacidity, in turn, increases the spasm of the pylorus, so that a vicious circle is formed, which is relieved but not cured by lavage.

Two rival operations, gastroenterostomy and pyloroplasty, afford a radical cure. The mortality of these operations is not great and about equal, and the complete relief of the chronic invalidism involved in the condition more than justifies the risk involved. This is one of the more recent successes of abdominal surgery in a field recently treated only medically with an unsatisfactory result.

In addition, there are other conditions of the stomach which are most radically and best treated by operative means. These conditions, which I will merely name, are simple dilatation, gastroptosis, hour-glass stomach, and adhesions about the stomach. None the less, imperative is an early diagnosis in case of intestinal obstruction, especially so in acute obstruction. The result of treatment, which must be surgical, will be found much better the earlier such treatment by operation is undertaken. The responsibility for such early treatment by surgical operation rests largely with physicians, who are the first to be consulted in all such cases. A strong suspicion is enough for the resort to operative exploration, which is comparatively safe in the early stages, and the relief of the condition is easier and more certain at this time. Don't wait for a positive diagnosis, for an operation is then a desperate and last resort, the poor results of which prejudice not only the laity, but the profession against operative treatment. I am inclined to think that it would be of ultimate benefit to refuse operation in such cases. In obstruction of a less acute character, especially in the case of those of middle life, or beyond, where the cause is likely to be a carcinoma of the large intestine, immediate operation is not so imperative, but the earlier the operation the better the prognosis. I have seen three such cases during the past eight months, and in these, as in most others, obstruction came on with no, or almost no, previous symptoms to indicate the presence of the new growth. Notwithstanding the fact that the condition cannot be diagnosed until it has grown so as to produce obstruction, it is sometimes practicable to remove the growth, as the lymphatic involvement seems to be a late development. This I found to be the case in a patient recently operated upon at the Presbyterian Hospital; but, unfortunately, pneumonia developed on the fourth day and proved fatal.

There is another abdominal condition much more common than those heretofore considered, in which the co-operation of the physician and surgeon is most essential. I refer to appendicitis. It has become somewhat of a hackneyed subject, so as almost to demand an apology for its consideration. But I ask no apology for speaking of it, as I believe that it has not been threshed out, especially before a mixed audience of physicians and surgeons like the present. I wish to emphasize certain points

Appendicitis is a surgical disease as to its treatment. In other words, the surgeon should be called in at once; the diagnosis, which is usually easy, is made. He should supervise the treatment and decide when and whether to operate during the attack or in the interval. It is unfair to the surgeon to delay asking him to operate until the condition is so desperate that the result or even th-

[1] *Annals of Surgery*, July, 1901.

expediency of the operation is very doubtful. It discredits the operation in the eyes of the laity, and the result is occasionally seen in the tone of the daily press in speaking of the subject. Still more is it unfair to the patient not to afford him at once the skill and knowledge of the surgeon, which are born of experience in treating many cases in all kinds of condition. I am more and more impressed with the facts the longer my experience becomes. Either the above practice should be followed or the dictum must be—operate in appendicitis as soon as the diagnosis is made.

The latter plan I have never professed or practised, though it has much to commend it, especially if appendicitis is not considered a surgical disease and the surgeon is not called in to supervise the treatment. I am not a believer in operation in every case as soon as the diagnosis is made, because I believe that a large number of cases can, under proper safeguards and careful watching, be allowed to recover from the attack, and because I believe that there are certain advantages in the interval operation in regard to the safety of the patient and the freedom from danger of ventral hernia. The leucocytosis helps us in our decision. If it is high or steadily increasing and the symptoms are marked, operation is safer; if it is low or decreasing, operation may be delayed, provided the symptoms do not clearly indicate it. The leucocyte count, without reference to the symptoms, is not to be depended on, for so many conditions may cause it to vary. With the above limitations, I have used the leucocyte count and found it serviceable. I have always felt it safe and proper, if after twenty-four or thirty-six hours *all* the salient symptoms steadily decline, to wait for the interval, provided the case can be closely watched. There are other cases in which as soon as seen, perhaps within twenty-four hours of the onset, we feel that immediate operation is the only safe course.

The difficulty lies in the fact that it is a treacherous and uncertain disease, and no one can give a definite prognosis in a given case at the outset. I have operated within twenty-four hours of the onset of the attack and found a sero-pus free in the pelvis and the lower part of the peritoneal cavity. When seen early, within twenty-four or thirty-six hours, I am more and more inclined to operate at once if the attack is a sharp one or moderately so, and is continuing or increasing in severity and the local symptoms are marked. If any drainage is required, it is usually but for a short time, and the case is practically like an interval operation, as far as danger of hernia is concerned.

Dieulafoy has called particular attention to the "treacherous calm" which may suddenly supervene in an acute case. Most of the acute symptoms suddenly subside, so that the patient, his friends, and often his physician are deceived as to the prognosis, and the necessary operation is dangerously delayed. A rapid pulse and some tenderness persist, and distention of the abdomen commences. This apparent subsidence of the attack marks a perforation of the appendix, the relief of its tension, and a commencing general peritonitis. It is most important not to mistake this sudden calm for a real improvement.

The same author well says that even in the mildest and most benign group of cases a safe prognosis is impossible on account of the manifold accidents that may surprise us.

The uncertainty of prognosis is illustrated by a patient I operated upon at the Presbyterian Hospital within the past three weeks, after an illness of three days. His pulse was never over 88, and usually lower, and his highest temperature a little over 100° F., yet because his local tenderness, which was not excessive, did not diminish, but perhaps slightly increased, I operated instead of waiting for the interval, as had been the intention.

The appendix was found completely gangrenous from its tip to within half an inch of its base, and it was only partly inclosed by adhesions. Fortunately, perforation had not yet taken place. Other experiences of a similar character have led me to be more conservative in delaying, and more ready to operate early, if any one symptom indicates it, in the interest of the patient's safety.

I am aware that the criticism itself suggests to many members of this society that the above may be the ideal practice and possible only in cities or larger towns, but not outside. A physician practising in a country district, one hundred miles or so from New York, where the means of almost all the people forbade the calling in of a good surgeon, told me recently that appendicitis was a disease he particularly dreaded on account of its uncertain outcome, and the inability to command surgical aid. But this can hardly be said by the profession in Westchester County, with your many towns of large size where the profession is specialized, and on account of your nearness to New York City. It is quite possible for many of you, therefore, to treat appendicitis in this "ideal" way, and all of you can call in a surgeon if a case is not doing well after appropriate treatment (*i. e.* rest, local application of cold, cleaning out the bowels, and abstention from opiates), thirty-six or forty-eight hours after the onset of the attack, or earlier, if the case is progressively severe.

From what has been said, it is evident that some risks must be taken in this latter manner of treatment, although it is still regarded by some conservatives as unnecessarily radical.

In the above we have considered the subject from the standpoint of the safety of the patient, and the attempt to diminish the *unnecessary* element of the mortality. But there is another side of the case to which I wish to call your attention. If we delay operation until an abscess is formed, we not only run the risk of the spread of the inflammation in case of an imperfectly shut-in abscess or of the bursting of the abscess, but we must drain the wound and thus delay its healing. The danger in this is the occurrence of post-operative hernia. The reality of this danger is seen in the fact, stated by Coley, that at the Hospital for the Ruptured and Crippled in twenty-three months there were observed fifty-five cases of hernia following operations for appendicitis, and "in a large majority of the cases there had evidently been suppuration during the healing of the wound." Post-operative ventral hernia should never follow an internal operation, or one done so early that drainage is not necessary, if the muscle-splitting method is followed. I discussed this subject in a paper read before the New York Clinical Society a year and a half ago, and pointed out some of the means at our command to diminish the period of drainage, shorten the time of healing, and thereby lessen the danger of hernia in pus cases. Some of these means were, (1) Removal of the appendix in all cases when possible; (2) Early removal of the gauze drain (second or third day), facilitated by a rubber tissue collar when it passes through the wound. This early removal of the drain allows the walls of the cavity or sinus to become approximated by the intra-abdominal pressure, and avoids the necessity of its slowly filling up by granulations. The first drain may be replaced for a short time by a shorter one, or by strips of rubber tissue folded up, and when the purulent discharge diminishes, 5-per-cent. boric-acid ointment is injected.

(3) Suturing, by layers, of most of the wound, and the use of provisional or secondary sutures in the part left open for drainage. By this method of treatment, I have obtained complete and firm union in a considerable number of appendicular abscesses in a fraction over fifteen days on the average. But the best safeguard is the use of the muscle-splitting method, which of late I have used almost altogether in the pus cases also, and found it to give ample exposure, even where, as in four recent cases, there was free pus in the pelvis. It may well be combined with the early removal of the drainage. Some have failed to secure enough room by this method; but, if necessary, the deeper aponeurotic layers may be incised downward or upward along the outer border of the rectus and so additional room be secured, or the sheath of the rectus may be incised to or toward the median line, and the muscle retracted in that direction. For any one not thoroughly accustomed to the muscle-splitting method, it may be wiser to incise the muscles in the line of the oblique incision, and run the risk of hernia rather than of the safety of the patient. Incisions in the semilunar line are more liable to hernia, and weaken the abdominal wall. The lesson from the relative frequency of hernia after pus cases is to operate early, and it is an answer to the charge that surgeons are too eager to operate for appendicitis, expressed not only by laymen, but by some physicians who would defer operation until the chance of success is diminished, and the danger of post-operative hernia is increased.

In general, make an early diagnosis, regard the case as surgical, and if the case is a mild one, or soon becomes so, aim at an interval operation, but watch the symptoms and the patient closely. If the case is severe or progressive, operate early, so as to nip in the bud a possible progressive peritonitis; if only seen after an abscess has formed, operate at once. This practice will conduce to the safety of the patient and the avoidance of hernia. I have not attempted to include all or even a majority of "borderland" conditions, for time does not permit of more than the mention of cirrhosis of the liver treated by establishing a collateral circulation between the portal and systemic veins, by adhesions of the omentum, liver, or spleen, with the abdominal wall; also, of abscess, gangrene, and even tuberculosis of the lungs, treated surgically, and many others conditions of the pelvis and head, to which surgical treatment has been recently extended.

In conclusion, improvement is needed in medical practice in the line of early diagnosis, especially in cases of malignant new growth and septic processes. Along these lines much has already been done, but much remains to be done, and a vast amount of scientific work is being applied to the problem. The responsibility rests on physicians, not only to make an early diagnosis, but to call in the surgeon to confirm the diagnosis, and to apply the appropriate treatment in that ever-increasing range of conditions in which operative treatment affords the best results.

THE EXPECTANT TREATMENT.

By ROBERT H BAKEWELL M D
AUCKLAND, NEW ZEALAND.
MEMBER AND LICENTIATE IN MIDWIFERY OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND ETC

To the great majority of readers under the age of fifty, the words at the head of this article will be nearly destitute of meaning. To some of the older men it may recall a period in the fifties when on the Continent of Europe, and especially in Vienna, was employed a method of treatment, more particularly of acute diseases, which had for its basis non-interference by any active measures, with that general tendency to recovery which characterizes even in the most fatal acute diseases, such as Asiatic cholera and yellow fever.

To a very limited extent, and almost wholly in hospital practice, the method was employed in England, but the condition of the profession then, so different from anything that exists elsewhere in Europe, precluded anything like the general adoption of the system. The "expectant" system was, as I have implied, based on the unquestionable fact that the majority of acute cases will end in recovery, if left to themselves, and just supplied with some form of nutriment and with fresh air. It was a period when the homœopathic system was very fashionable, not merely the *similia similibus curantur*, but the infinitesimal doses. There were thousands of the best-educated persons in Great Britain, France, and Germany who firmly believed in the efficacy of a billionth of a grain of rhus, or of a drop of tincture of aconite. Hospitals were established in which patients were treated by such doses, and in which nothing more was done for the patients except to feed them properly, give them as pure air as can be obtained in a city, and apply a cataplasm or a fomentation or a wet compress, to allay some local pain.

The curious thing was that not only did the majority of the patients recover, but that a larger proportion recovered than in hospitals, where the old anti-phlogistic method, or the brandy and beef-tea method, was adopted; and still more marvelous did we regular practitioners find it, that the patients recovered more quickly, and the convalescents suffered less than under our system. This is what the few among us who condescended to visit and examine the cases at homœopathic hospitals were forced to acknowledge.

Now, putting aside the infinitesimal doses, which certainly could have had no physical effect, though they unquestionably exercised a powerful psychical effect, some physicians, not yet too old to learn, set themselves to investigate what had never yet been studied, and what is scarcely ever nowadays even thought of—the natural history of disease. How does a case, say, of acute croupous pneumonia begin, progress, and end, when not interfered with by any active treatment?

Such a case in any man under sixty, and in some above that age, would in the early fifties have been treated by two out of three of the physicians for in-patients in the hospital of which I was a student (the Middlesex Hospital, London) by the old anti-phlogistic treatment. Milk diet; venesection to twenty ounces the day of admission; calomel gr. ij, pulv. opii gr. ½, antimon. et potass. tart. gr. ½, every four hours. Perhaps, a larger dose of the tartar emetic would have been given in a saline mixture, until vomiting occurred. The next day, there would have been a repetition of the bleeding, either from a vein or by means of cupping glasses, to the amount of ten or twelve ounces. The calomel and opium and the tartar emetic would be continued. The third day the same medicines, with a dozen leeches to the chest. The calomel would by this time have begun to affect the mouth, and then some milder form of mercurial, such as gray powder or blue pill, would be substituted. This would be continued until the solidified being had recovered its function, and respiration was heard all over it.

Then, the patient would be carefully fed up during a long period of convalescence, and would have thought himself fortunate if discharged cured at the end of six weeks' treatment. During all this time he would have been taking some kind of drug at least three times a day. If there had been any pleuritis with effusion, cantharides, blisters, or iodine paint,

to the point of blistering, would have been applied to the chest.

The third physician, a much younger man than his two seniors, would probably have either tried the expectant plan or the brandy treatment which was just then and for a few years all the rage in London, six, eight, or even ten ounces of brandy in the twenty-four hours.

The expectant treatment of such a case would be: Jacket poultices, renewed every four hours to the affected side; a pill made of bread or extract of grass, and a draught of colored water every four hours as a placebo; milk diet for the first few days; perfect rest for the lungs, no talking allowed, and a more nourishing diet as the case improved. When redux crepitation was fairly established, probably meat and wine would be given, and the poultices would be discontinued.

Under such treatment, supposing the patient admitted were under fifty and of fairly healthy habits as regards drink, he would be convalescent in ten days or less. The mortality, when only one lung was affected, was *nil*. By this I mean that one lung should be almost free from inflammation—a touch at the base of the other would not count.

In England, we did not follow out the expectant treatment quite so rigorously as they did in Vienna. When there was acute pain, I question whether any of us would have abstained from the use of opium or morphine. Certainly, I never did. And when the temperature was high with a dry skin, we should have used the wet pack, warm. In typhoid fever, we always used a pack round the lower part of the trunk, and I followed Dr. King Chambers' (of St. Mary's Hospital, London) plan of giving twenty minims of dilute muriatic acid every four hours in the colored water, in order to aid the digestion. With this treatment, I had only three deaths in a batch of ninety-seven cases, chiefly among negroes and the lower class of colored people in Trinidad, British West Indies. They were treated in their own houses under every disadvantage.

Now, when I see any new method of treatment vaunted, I always ask myself, have the people who advocate it any idea of what is the natural rate of death and recovery from this disease? Suppose, they say that their treatment cures 90 per cent; how many per cent. would die under an expectant treatment?

It is not often one is able to get any large series of cases that have had no medical treatment from first to last, but it was my good fortune, as medical officer of health for the colony of Trinidad, to be able to investigate such a series. In the year 1870, the inhabitants of a district on the east coast of the island memorialized the governor to send them a doctor, as for several months they had been suffering from a severe epidemic of acute dysentery, which had attacked six hundred out of eight hundred of the inhabitants of the district. These people, with the exception of the French priest and a government officer, were all colored, and most of them pure negroes. They were densely ignorant and superstitious, and their treatment, such as it was, was barbarous in the extreme. For instance, when sloughing of the rectum took place, as it did in the worst cases, their treatment was to stuff the rectum with some boiled herbs. They had been living for months almost entirely on fish—mostly salt—and Indian corn. All their ground provisions, such as yams, had been destroyed by a prolonged drought. I was sent over to investigate the matter. I found that some months previously a woman had come over from the capital—about sixty miles through the bush—and the day after her arrival was attacked with acute dysentery, of which she died. From her the disease spread to six hundred other persons. Even among these persons, all suffering more or less from scurvy and without any medical treatment, the mortality was only sixty, that is 10 per cent.

I made my report to the governor, and he sent fresh provisions, vegetables, and cattle, also medicines and a dispenser. I took over 111 cases, residing in a strip of coast sixty miles long. I used to ride out every day with a supply of medicines in my saddlebags, chiefly one-grain opium pills, and I lost only four out of the 111, and they were very ill when I commenced their treatment. All, therefore, that medical aid and the much more powerful aid of good food did was to save about 6 or 7 per cent.—not 94 per cent. as the moderns would have reckoned it.

I may say, before I conclude, that colored water and pills as placebos are indispensable in the expectant treatment. The public will not believe in it; they want some objective on which to pin their faith. And they must not have the faintest suspicion that no active treatment is being used, otherwise they will immediately leave the hospital, or in private practice send for some one else.

I suppose that every septuagenarian is more or less *laudator temporis acti*, but in my own justification I must say that I am terrified when I see the mortality of some modern treatments, and contrast it with that of the good old times. Take diphtheria, for example. I have attended cases of that disease ever since it first appeared in London; I have seen it in that city in large towns in England, in the West Indies, and here in New Zealand, and I have never had, for any series of one hundred cases, anything like the mortality that is supposed to be a matter of congratulation under the antitoxin treatment. I have had as many as twenty-two cases in succession, without a single death. The mortality of typhoid fever under the milk and perchloride-of-mercury treatment is to my mind shocking.

I wish to say a few words on the present system of reporting cases, as contrasted with the careful method of my younger days, but I had better not weary the readers with any more of the maunderings of an old man, whose medical education commenced in 1848. I may be allowed, however, to add a few words as to the effects on the minds of students who saw the expectant treatment carried out by their seniors. The first effect was to make us medical agnostics: we believed in nothing but the reparative powers of Nature. Then, as the responsibilities of practice came upon us, and we were compelled to do something to relieve pain and other urgent symptoms, we found that besides rest, food, and the simple applications of the expectant method, there were powerful drugs that unquestionably expedited a cure, when a cure was possible, and relieved suffering even when death was inevitable. We used opium and belladonna and their alkaloids, quinine for malaria, mercury and potassium iodide for syphilis, arsenic for many skin diseases, and purgatives and occasionally calomel or blue pill. But instead of using the enormous doses of our predecessors, we carefully tried the minimum dose that would produce the desired effect. We laid more emphasis on rest and sanitary measures than our predecessors, and we urged preventive measures when the constitution of the patient was at fault.

Those of us who are left *rari nantes in gurgite vasto*, are shocked and horrified at the brutal and barbarous methods, both medical and surgical, of the present day: at the huge doses of powerful medicines poured into the stomachs, or injected under the skin of sick persons; at the bloody and protracted operations for the removal of diseased tissues, as if cutting

off or cutting out a diseased portion of the body could ever be called a cure, and we thank God (even if in this we resemble the Pharisee in the Gospel) that we are not as these other and younger men, and that if Nature does not always succeed in curing our patients, we do not kill them!

THE PSYCHIC HALF.

By J. ALLEN GILBERT, PH.D., M.D.,
PORTLAND, ORE.

It would seem that nowadays all appeals to medical men must be made in the atmosphere of laboratories, operating rooms, *x*-ray machines, microscopes, test tubes, and the like, else one runs the risk of being classed as a heretic, and being cast from the roll of a respectable physician into the outer darkness reserved for quacks and charlatans. A review of the tendencies in modern medicine almost makes one feel that psychology has sold her birthright to physiology, physics, chemistry, and kindred objective sciences, and fears to enter an appeal for that psychic aspect of man which makes him what he is.

All men seem to agree to general statements in regard to mind, but many, when pushed to more definite explanations, either deny the existence of mind as such, or involve themselves in a hopeless tangle of contradictions in attempting to explain it in terms of physics. The present age seems to be running riot in its devotion to the sciences which admit of statistics, computations, and demonstrations, apparently forgetful of the fact that not all truth and not all reality can be subjected to the various methods at the disposal of the so-called objective sciences. All praise to scientific investigation, whether in lines of physiology, chemistry, psychology, or what not; but some of the devotees to statistical methods have expressed their hope of seeing the time when the laws of the mind's activity can be given in tables and formulæ as exact and precise as those of mathematics and astronomy. Admirable as their aspirations may be, one is forced to smile at the narrowness of their conception of conscious life, and is almost impelled to ridicule a postulate which so completely inverts relations as to presuppose a law of causation back of ultimate reality. To take time to emphasize the value of laboratory work and the mechanical accessories and helps to investigation would be to rehearse that which even the laity appreciate; and so, in emphasizing the psychic side of man, the other aspect is not lost sight of in the least, for our present advancement is due largely to the experimental tendency which characterizes recent decades.

Whatever our conceptions may be as to the relation and individual nature of mind and body, thought demands reference to an ultimate unit; and both mind and body must have their roots piercing back into one ultimate reality—call that reality what you please. Religion calls it God, philosophy calls it the absolute, science calls it nature, physics calls it force, psychology calls it mind—all names for one and the same entity.

It is almost instinctive in man to ask for an explanation of how human consciousness springs into existence. The fact is "you are," "I am," and every man knows that "he is." Mind is known by direct experience, and agnosticism refutes itself by the mere statement of its theory; for knowledge is a precondition of theory and discussion. Is one to be criticised for dogmatizing on the fact of knowledge, for accepting knowledge without question? It is the basis of criticism, and any attempt to undermine knowledge is futile; for in so doing the fact of knowledge is established beyond dispute. It is the *sine qua non* of self-conscious life, and only by knowing do we spring into existence as objects for psychological data. Physiology and biology fail utterly to explain it, and it is not only unjust, but unscientific to demand that psychology shall assert and defend herself in terms of sciences entirely foreign to her true nature. That science which rejects a fact is guilty of treason; and if there is any fact which stands out unique in that it needs no proof, it is the fact "you are—I am;" and every man, when he says it to and of himself, thinks not of his body, but of that inner process of consciousness which is to him—for the time being, at least—convincingly real. It is a strange paradox that throughout the history of thought men have demanded proof that they exist; and, failing to get such proof, have relapsed into agnosticism, which is in itself a theory of knowledge. It is still more queer that men do not hesitate to give objects in the external world an abiding reality, and yet deny reality to that consciousness upon which so-called things are dependent for their existence as things—mark you, "existence as things," not "existence." We often forget that things as such are constructed through a process of perception—tedious and irksome at first, to be sure, but soon accomplished with such ease and rapidity that we are prone to deny the existence of the process at all. It would seem incontestable that either mind is real and an entity, or we have no right to speak of the effect of mind upon body. Non-entities can *do* nothing, and simply *are not;* for things only gain their existence and their reality by manifesting themselves by some sort of activity; and, furthermore, that which is able to manifest itself is entitled to reality, and may therefore be called an entity. At any rate, we cannot speak of the effect of a non-entity upon an entity.

All attempts to explain how molecular motion can account for, or be transformed into, conscious states imply two distinct separate entities, and plunge one into the fallacies of a materialism, or a dualism with materialistic basis. Several years ago, a fellow-teacher advocated the doctrine that the stomach was the first organ to appear in animal life, and all else had its origin in this stomach. Consciousness also was evolved from this same fountain of existence. As he put it: "If the fumes of the stomach mounted upward, they became consciousness; if they descended in their course, they passed as débris from the system." Such expressions can be nothing but figurative, and yet, is the idea involved any more inconsistent than when Spencer says: "The quick succession of changes in a ganglion, implying, as it does, perpetual experiences of differences and likenesses, constitutes the raw material of consciousness?" nor does it become more consistent by Huxley's explaining the mind as an interaction of atoms; nor does one feel more enlightened when Carl Vogt says: "As contraction is the function of a muscle, or as the kidneys secrete urine, so, and in the same way, does the brain generate thought, movements, and feelings." All such statements are based upon a sworn allegiance to the atomic theory, and the atomic theory has absolutely nothing to do with consciousness as such; space, which is but a category of mind, has no objective reality, and yet, in our carelessness of thought, we not only give space objective reality, but endeavor to subject mental phenomena to its limitations, and describe all conscious processes in spatial terms, forgetting that a unit of consciousness cannot arise from the mere combination of individual parts. Comparison, judgment, criticism, admiration, and the like, all imply a unit; and where, pray, is unity to be found in brain tissue, or even in the atomic theory, where unity is but hypothetical? Mind cannot be considered as a sum; but, on the contrary, it is the only unit known in

science, and from this unity of consciousness as a starting point we construct our sciences. By this unit, and this alone, can qualities and attributes be synthetically unified into things. Things are one, because, and only because, we *make* them one. The simplest of so-called things is a thing not because it, so to speak, has length, breadth, thickness, color, weight, hardness, roughness, etc., but because these varied elements are unified and given meaning in consciousness; and the unity, which consciousness is, is carried over into things, thus constructed through a process of sensation, perception, apperception, with objectification. Such a conception does not, in the least, rob things of their reality; but, on the contrary, gives them a vivified existence and a reality which pulsates with a warmth that helps us to look upon things as our fellows indeed. Instead of dead, inert substance, to which we owe our existence, we find confronting us a coworker, as it were, in that great throbbing reality which we call Nature. In the diversity of Nature is, after all, the best proof of an underlying unity. And also in consciousness. The very inception of unity is when the child, for instance, playing with his toe, realizes that he is not his toe, but that "he is he," or what is equivalent —that "he is." There is the beginning of human thought—that beginning which is, which must be, an unsolved enigma. All explanation begins and ends in the unexplained. To explain the simplest fact in the Universe is to explain the Universe; and, moreover, to explain scientifically is not to explain exhaustively.

"Flower in the crannied wall,
I pluck you out of the crannies,
I hold you here, root and all, in my hand,
Little flower—but if I could understand
What you are, root and all, and all in all,
I should know what God and man is."

The highest desideratum of the physical sciences is an absolute unit upon which to base their deductions and inductions. Instead of reducing the multiplicity presented to our sciences, research only increases it. The farther chemistry pushes her tests, the more so-called units she thrusts into the list of elements. In time the atomic theory will—yes, must—go under, even as the old corpuscular theory of light, for it has contradictions upon its very face. Even at best its unit—the atom—is a hypothetical unit, based by analogy upon the unit of consciousness. When we speak of the effect of mind on body, or when we speak of giving certain treatment for moral effect, are we using mere terms to fill in a gap—a mere worn expression to cover up ignorance—or are we in reality paying tribute to an entity which must be taken into consideration in our etiology and pathology? It is aptly said when we say, "Man's body." He who treats patients has more than a mere disease to handle. When we call man a cognitive, social, political, esthetical, and moral being, do we not carry him in a sense above the realm of physiology and beyond mere medication? How much of the physical organism is to be found in such terms as history, philology, politics, morals, theology, philosophy, sociology, and jurisprudence? Meager, indeed, would be our literature if they were removed; and, yet, what are they but records of ideals!

"In man's self arise
August anticipations, symbols, types,
Of a dim splendor ever on before."

But what will neurology and physiology do with an ideal? How will they classify an ambition? Where will they locate a compunction of conscience, or a noble determination? We laugh at Descartes for assuming that the pineal gland was the seat of the so-called soul. We repeat our smile as the throne of psychic life is transferred to the pituitary body; but are we more consistent when we label the frontal lobes "higher psychic life?" Where is the mind? Nowhere. Space and space-terms have no reference whatever to consciousness as such.

View the subject for a moment from the standpoint of esthetics. A thing is beautiful or ugly, because it attracts or repels an esthetic being in whom relation and comparison are possible. Standing at the summit of some mountain ridge, where all shades and shapes of wildness and civilization blend to form one magnificent panorama, all we can do is to exclaim, beautiful! But stop a moment. Analyze that conception. Where is the beauty? Is it in the water, in this tree or that grass plot, in yonder train or village, in cloud or sun? Whence, I repeat, comes that beauty? What wrests from this multiplicity and diversity the unitary conception of the beautiful? The physical sciences can do absolutely nothing with such conceptions as the beautiful and sublime. Why? Because the physical sciences have no real unit through which relation and unification become possible.

Now, a glance at the moral aspect. Reality as such cannot be subjected thoroughly to the physical law of causation. Entities act, and from the activity of these entities we formulate a law of causation. Ultimate reality merely manifests itself, and because it is self-consistent, we deduce the laws of its activity; and then, forgetting that they were deduced, we reverse the relation and put the law of causation back of reality. Men make laws, not laws men. A misconception of causation has led to nine-tenths of the prolific discussion on freedom and necessity. We have been taught time and again that man is what he is because of heredity, education, and environment. That is part, not all. By such a tenet, man is subjected thoroughly to the physical law of causation. It means that you deny man his self-activity, and it also forestalls the use of any such terms as "ought" and "ought not." Is man a mere effervescence from brain tissue, to be produced, to be acted upon from all sides, and upon whom moral responsibilities are imposed without any capability of reaction? On those terms, a McKinley is not one whit better than a Czolgosz, a hero no more to be admired than a villain, a king no nobler than the horse which he rides. In terms of causation, good and bad lose their meaning. Such terms as character, ideals, ambitions, heroism, and honor fade into a mere mockery, and vice, debauchery, and crime lose their hideousness. Courts of justice stand as a living monument to that psychic half in which alone is found the justification for "ought," and "ought not." Physical sciences can speak in terms of "shall" and "must," but never in terms of "ought." If consciousness and mental processes are but products of the brain, then give it attributes and qualities, but cease speaking of character and cease condemnation of fellow-men. The most rampant of materialists would scarcely claim that brain-processes or nerve-currents ought to do so and so, and yet they demand it of this so-called product of cerebration, even though they deny its entity. Take from the world "I ought" and "you ought," and you have taken from the world humanity. Take from the world mind as an entity, and you annul courts of justice and reduce the world to a mechanism in which manhood and rascality are reducible to the same basis, viz., a brain-process. Aggressive assertion of the psychic half is the very essence of manhood, and if there is any entity known to man, it is the reality—mind—asserting itself along the line of its own ideals.

Is medicine, then, justified in looking upon her field as one merely to deal with the physical? Be-

cause the poorly informed take up one idea—truthful in itself, perhaps—and make that one idea include all of the healing art, is no reason why those of broader mind should hoot at and reject this idea which was merely unfortunate in falling into the hands of advocates too ignorant, rampant, and fanatical. Christian Scientists, though they have rendered themselves ridiculous by the extent to which they have carried their tenets, have, nevertheless, incorporated in their doctrines a truth which is of value. We laugh at them with justice, and yet, has science of the so-called orthodox type always been perfectly staid in her positions?

Has not experimental psychology, for example, promised more than she has fulfilled or ever can fulfill? The field of medicine is man; and if, after proper study, man is decided to be moral, esthetical, and political, does not treatment at times reach beyond the materia medica and laboratory? On the other hand, if man in his entirety is capable of reduction to a mere nervous mechanism, should we not, at least, be consistent and cease speaking of the effect of mind, if we deny its entity and make it but a product? Where is the consistency in giving lectures upon "Mental Diseases" and denying the entity of mind? Is it not lecturing upon diseases of a non-entity? Why speak of mind and the effect of mind at all, if mind is not an entity? Is anything less real, less an entity, because to our means of perception it fails to establish its continuity in time? Must all being have length, breadth, and thickness before we will grant it existence and reality?

SPASMODIC BRONCHOSTENOSIS.

By ALBERT ABRAMS, M.D.
SAN FRANCISCO, CAL.

To my knowledge, this affection has heretofore enjoyed no specific place in our medical nomenclature. The affection in question must be dissociated from bronchostenosis as ordinarily interpreted, insomuch as the latter is, relatively speaking, a permanent, whereas the former is a transitory, condition. Spasmodic bronchostenosis is, practically, nought else but asthma without paroxysms.

Before describing the symptomatology of spasmodic bronchostenosis, I wish to refer succinctly to the bronchial musculature. The entire bronchial tree is provided with smooth muscular fibers which contract by irritation of the pneumogastric nerves and their branches. If in a dog a section is made of one vagus, relaxation of the bronchus on that side ensues. According to the conception of Biermer, the bronchial tubes are the antagonists of the inspiratory muscles in the same sense as the muscular coat of the arteries is antagonistic to the heart. The bronchial muscles, in other words, represent the so-called "lung tone," offering resistance to the volume of inspired air, and act, at the same time, in conjunction with the elasticity of the lung in promoting the act of expiration. Biermer contends that the bronchial musculature facilitates expectoration after a manner similar to other canals, like the ureter, œsophagus, intestine, etc., which are supplied with a muscular coat lined by mucosa. Whatever theory may be espoused in the pathogenesis of asthma, all clinicians agree that the spasm element plays an important rôle. I have already referred* to the production of typic asthmatic seizures in individuals subject to asthma, after impaction of cotton in one or both nasal cavities. If the nasal mucosa were previously cocainized, no paroxysms could be induced. This simple experiment shows that in susceptible persons bronchial spasm may be invoked by a stimulus acting indirectly on the vagi through the terminal fibers of the trigeminus. In the same contribution, I assumed the existence of two distinct functions of the vagus nerve, or, at any rate, the presence of nerve fibers with a dual function; nerve fibers which could dilate the longitudinally disposed muscular fibers of the bronchial tree (bronchodilator nerves), and nerve fibers which could contract the circularly disposed muscular fibers (bronchoconstrictor nerves). In the action of these two sets of nerves fibers, I saw an analogy in the vasoconstrictor and vasodilator nerves of the vasomotor system.

Etiology.—As in true nervous asthma, a nervous element is the most prominent feature of bronchial spasm, other changes being either absent or secondary. More often, the bronchial spasm may occur coincidently with an attack of bronchitis, and this is the more frequent form of the affection.

Symptomatology. In bronchospasm, associated with bronchitis, we have all the symptoms of the latter affection plus a spasmodic cough, which is exceedingly distressing to the patient and usually resists the conventional expectorants. If the spasmodic element predominates in bronchitis, the sputa are scant and viscid. The spasmodic cough, the concomitant of spasmodic bronchostenosis may persist for an indefinite period after resolution of the bronchial catarrh. If we auscultate the chest of a patient with bronchitis in whom is associated bronchial spasm, we hear in addition to the usual râles of bronchitis, dry, squeaking, and groaning sounds which, unlike those in bronchitis, are chiefly expiratory with prolonged and accentuated expiration. In differentiating the râles of bronchial spasm from those of bronchitis, I have recourse to the inhalation of a few drops of nitrite of amyl, a manœuver which I have described elsewhere.† Such inhalation carried to its physiologic effect will temporarily dispel râles due to bronchial spasm, while on the râles of bronchitis no effect is produced. In spasmodic bronchostenosis independent of bronchitis, the ordinary physical methods of examination are, as a rule, negative, and the diagnosis may be verified only by treatment, for which affection iodide of potassium is virtually a specific. Occasionally, one hears after repeated auscultation, when the patient is instructed to practise forced expiration, wheezing sounds which are more manifest over the large than the small bronchi. An invariable subjective symptom is a persistent spasmodic cough which is resistant to ordinary medication. Associated with the cough at times is slight dyspnœa with a feeling of constriction about the chest, which is invariably aggravated at night. If asthmatic paroxysms should ensue from the bronchial spasm, they are always ill-defined and of short duration. Expectoration is slight or absent, and free expectoration always signalizes a suspension of the bronchial spasm. Like the cough of nervous asthma, the cough in bronchial spasms may be relieved by the most varied conditions, among which the influence of climate is paramount. In a cold and damp atmosphere, bronchial spasm is especially common. A transfer to dry climates and high altitudes, or even any change of locality, may cause an almost miraculous disappearance of the cough, even after medication has been most persistent and has failed. Errors in diet also constitute a common factor in bronchial spasm, and I have frequently noted its disappearance after correction of a gastric affection. I believe that many of the "stomach coughs," so called, are due to bronchial spasm.

Treatment.—Many cases designated as bronchitis

* Heretofore Undescribed Neurosis of the Lungs, *New York Medical Journal*, June 13, 1896.

† Drugs in Diagnosis, *Am. Med. and Surg. Bulletin*, October 10, 1898.

are merely cases of bronchial spasm, for which there is only one remedy, and that is climatic change. As in asthma, every individual with spasmodic bronchostenosis is a law to himself, as regards climate. I wish particularly to emphasize the value of the iodide of potassium in bronchial spasm.

In my experience it is a specific, but it must be given with circumspection in this as well as in other diseases in which its action is extolled. A medium daily dose is about 30 grains, although a daily dose of 60 grains is not excessive, when no idiosyncrasy is displayed toward the drug. We must guard against iodism, especially iodism of the mucous membrane, which manifests itself as œdema and acute inflammation.

We must not forget the observation of Neumann, viz., the occurrence of a tuberculous iodide eruption on the stomach mucosa, similar to the tuberculous skin eruption. Iodide of potassium by provoking tracheobronchitis may induce a paroxysm not unlike that of asthma, and, furthermore, it may induce acute pulmonic congestion, as noted by Fournier in his "Traitement de la Syphilis." Individuals with a defective renal apparatus are particularly liable to the development of iodism. Tincture of iodine in 10-30 drop doses in water may be substituted for the iodide of potassium in those who show an idiosyncrasy toward the latter drug. The promotion of diuresis by drinking largely of water or milk may prove a means of obviating iodism. Belladonna, in the form of the tincture (5 drops) with each dose of iodide of potassium, will prevent the objectionable iodide coryza. Should the iodide cause digestive disturbances, Fowler's solution may be given concurrently. Briquet suggests bicarbonate of sodium in overcoming iodism, and sulphanilic acid has been given for a similar purpose.

The following formula is of value in certain cases of spasmodic bronchostenosis:

℞ Iodide of potassium..... 5 drachms.
Tincture of lobelia..... ... 10 drachms.
Spirits of glonoin (1 per cent.)... 16 minims.
Elixir bromide of potassium.. to 4 ounces.

Mix. A teaspoonful three times a day after meals.

This dose may be gradually increased if necessary.

THE HEMORRHAGIC DIATHESIS IN RELATION TO OPERATION ON THE NOSE AND THROAT.

By E. HARRISON GRIFFIN, M.D.

NEW YORK.

LECTURER ON DISEASES OF THE NOSE AND THROAT IN THE NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT OF BELLEVUE HOSPITAL OUTDOOR POOR.

I do not know if the patient with a hemorrhagic diathesis is more prone to tell an untruth than one who has the normal blood circulating through his anatomy, but I have found it to be a fact that it is impossible to obtain a history of bleeding until after an operation has been performed, and we are face to face with the fact that we have operated in a hemorrhagic case. I invariably ask a set of questions previous to an operation to ascertain if my patient belongs to that class known as the bleeders. My answers have always been negative.

These patients are generally anxious for an operation if one is indicated, and will generally deny the fact that the slightest cut will produce an excessive hemorrhage.

A number of cases are on record in which the unfortunate possessor of this diathesis has lost his life through the error of not informing the surgeon that he bled, and bled profusely, after the slightest cut.

These cases will tax the ingenuity of the surgeon to the utmost, and will greatly shake his belief in all astringents after he has tried one after another to control this class of hemorrhage, and found them all to fail. Even the suprarenal extract he will discard in a true case of hemorrhagic diathesis as useless, and wonder where it received its reputation as a hemostatic.

Miss B. was referred to me by Dr. Richardson on account of a nasal obstruction, which interfered with the proper nasal breathing.

An examination showed a marked hypertrophy of the inferior turbinated bone on the left side, which impinged upon the septum and interfered with her breathing space. Miss B. was a brunette, aged about twenty-two, slight in build, and weighing about one hundred pounds. The nature of the operation was explained to her, and she readily gave her assent to have it performed.

She was placed under the quinine treatment for two weeks, and a day was then set for the operation. Miss B. was questioned in regard to any hemorrhagic diathesis, and all my inquiries met with a negative answer. The nose was treated with cocaine and the suprarenal solution, as is customary in these cases. The operation was without incident. The lower section of the turbinated bone was removed on the left side. The hemorrhage during the operation and immediately following it was about the normal amount that is customarily found in an operation in this region.

The nose was plugged from the anterior portion by a series of plugs, the operator carrying the first well back and then plugging upon top of that again. The post-pharyngeal hemorrhage was controlled by the introduction of the first plug.

Upon interrogating my patient as to how she felt, she replied: "Fine; I did not have any pain and did not have any discomfort." I directed her to sit in my front office for a time, when I would look at her again, to be sure that there was no bleeding. She told her sister that the operation was nothing, and that she was not going home directly when she left my office, but was going shopping.

Fifteen minutes after this, she knocked at the door, and told me that her nose was bleeding. I found blood streaming from the anterior part of the nose, and pouring in large quantities down the posterior pharynx. The latter she was swallowing. I removed the plugs, and immediately substituted a new series, carrying these plugs farther back, and after a great deal of trouble, was able to control the hemorrhage. After the nose was plugged and the posterior and anterior nasal bleeding was subdued, the hemorrhage continued through the eye by way of the lachrymal duct. I wiped the eye again and again, to relieve her discomfort. The escape of blood through this channel continued for over half an hour after the posterior and anterior nasal hemorrhage had been conquered.

When the hemorrhage was once controlled, she began to complain of intense pains in her abdomen. Her sister who was with her told me that this was caused by her sickness which was now due, during which period the patient suffered intense agony. Miss B. was now attacked by profuse vomiting, ejecting the clotted blood that had run down her pharynx into her stomach. She vomited enough clotted blood to fill a large cuspidor I had in my office. The exertion of the vomiting brought on hemorrhage again from both the anterior and the posterior nares.

I now placed Miss B. prone on her back and gave her one-fourth grain of morphine. Before this had time to act, she had another attack of vomiting. The

same amount of morphine was repeated in half an hour.

This quieted the case and subdued the hemorrhage. Morphine I consider to-day acts better to control hemorrhage in a case like this than any other drug or series of drugs we have in the pharmacopœia. At four o'clock I accompanied her home in a cab, attended by her family physician, Dr. Richardson. She reached her home and was put to bed, without any recurrence of the hemorrhage. Morphine was again administered at half-past four o'clock. The patient was placed upon a milk diet and warned not to leave her bed until directed.

The operation was performed on Monday. On Tuesday one anterior plug was removed; two others were removed on Wednesday, and the last two on Thursday, and the patient was able to breathe through her nose. When I called Saturday, I gave my patient permission to sit up for two hours in the afternoon, but positively not longer. However, she left her bed at twelve o'clock, and in the evening entertained some friends until after twelve midnight.

At four o'clock, Sunday morning (six days after the operation), she awoke with blood streaming down her throat and pouring out of the front of her nose. The nearest physician was summoned and her brother came for me in a cab. Upon my arrival at the house, I found her bed, sheets, pillow cases, night-gown, and everything near, saturated with blood. The patient was still bleeding, notwithstanding the efforts of the local surgeon to control it by alumn water. I again plugged the nose, administered a dose of morphine, placed a trained nurse in attendance, and left strict injunctions that the patient must be kept absolutely quiet. There was a slight attack of vomiting after I left, which caused the hemorrhage to recur. The patient was kept in bed for two weeks and fed upon a soft diet. After this, she performed her usual avocation in life without incident.

The family history in this case is more than interesting, showing how patients will conceal the fact that they are bleeders, when they are desirous to have an operation performed. The mother bled for four days when she was a girl, after having a tooth extracted, and the hemorrhage was controlled only after a great deal of trouble. She bleeds to-day profusely, if she is scratched by a pin, or cuts her finger. The brother of the patient, aged about sixteen, bleeds copiously from his nose. He awakes often in the morning to find his pillow stained with blood, and the blood pouring from his throat and nostril. The slightest scratch produces an excessive hemorrhage.

Patient C., male, applied at my office to have his tonsil excised. He was questioned in regard to a hemorrhagic diathesis, but his answers were negative. The tonsil was excised at half-past ten one morning. Moderate bleeding occurred, which was followed soon after by a copious hemorrhage from the side of the cut. The patient was given ergotin and gallic acid internally, and various astringents were applied locally. Ice was used without any diminution of the bleeding. His mouth would fill with blood, which he discharged into a cuspidor. Direct compression was made over the cut surface by the finger covered with cotton. This seemed to irritate the throat and augmented the flow of blood.

The patient bled profusely from the time of the operation until four o'clock the same afternoon, when he had a fainting attack after taking a dose of one-fourth grain of morphine. The hemorrhage lessened considerably after he came out of the faint. I now removed him to a hospital.

There was a slight oozing of blood for two days. Upon the third day he left the hospital, very much against my will, and returned to his home. He had another hemorrhage on the fifth day after the operation; this was easily controlled. Ten days afterward he was back at his occupation of musician in one of our theaters.

A clear history of hemorrhagic diathesis was obtained after the operation. The slightest scratch would produce a hemorrhage. This history was obtained only after the operation had been performed.

Patient D., female, aged sixteen, applied at the clinic for hypertrophied tonsils. Both were removed by my associate, Dr. J. C. Sharp. Profuse hemorrhage followed the operation, and lasted off and on for one month, during which time she was confined to one of the wards of Bellevue Hospital. A history was obtained of hemorrhagic diathesis on her father's side. A cut by the razor in shaving would produce a loss of a considerable amount of blood. The patient recovered.

Patient E., male, applied at the clinic for an obstructed nose. His answers to a hemorrhagic diathesis were negative. This case is particularly interesting, for only one week previous to his applying to the clinic for an operation he came near bleeding to death and had to have a transfusion of milk to save his life. Still, one week afterward, he applied for an operation on his nose, and denied any knowledge of a hemorrhagic diathesis, although he was closely questioned in regard to bleeding from a scratch or a cut. Subsequently, he admitted bleeding upon the slightest injury, and losing blood to an enormous quantity, entirely out of proportion to the nature of the injury. This patient also recovered.

A case was related to me by Dr. Woodend, the surgeon of the Third Avenue Railroad, where an employee of the road had been operated upon for a deflected septum. The hemorrhage following the operation was so severe that he was sent to a hospital. He left the hospital three days after. A recurrence of the hemorrhage happened two days later, at which time the patient died. A hemorrhagic history was obtained.

The above cases will show how important it is to quiz one's patients in regard to the hemorrhagic diathesis, and at the same time to go into every detail. If an operation is in question, and the patient thinks such an operation will relieve his suffering, he is apt to give a rosy color to the situation, and will deny all knowledge of being a bleeder, and oftentimes a knife is introduced when the sequence will bring into action all the artifices that surgery can command.

112 West Forty-fifth Street.

THE TREATMENT OF XANTHOMA OF THE EYELIDS.

By FRED J. LEVISEUR, M.D.,
NEW YORK.

Rayer, who was the first to mention xanthoma, describes it as "yellowish patches on the eyelids and in their vicinity, resembling chamois leather, slightly elevated, soft, without heat and redness, often appearing symmetrically." Bazin speaks of it as "molusum cholestérique;" and Addison and Gull as "vitiligoidea," on account of its supposed similarity to Willan's vitiligo. Erasmus Wilson called it xanthelasma, which term is still in use, though it is more universally known by the name xanthoma, given to it by W. F. Smith.

To the above clinical description the following additions may be made: It is not hereditary nor congenital. It most frequently develops after puberty. Spontaneous involution, after the lesions have once become stationary, does not take place,

except perhaps by accidental traumatism. The region of the left upper eyelid (internal canthus) seems to be affected oftener and earlier than that of the right. Change to a malignant new growth is extremely rare, if occurring at all. Pollitzer of New York has proved that xanthoma of the eyelids is not a neoplasm, but the product of the degeneration of embryonically misplaced muscle fibers, and bears no histological relationship to xanthoma tuberosum disseminatum and xanthoma diabeticorum. A connection between xanthoma of the eyelids and systemic disturbances, particularly those of the liver, has not been established. People with dark complexions seem to be more liable to develop the affection, but it occurs also in those with light complexions. It has been very often noted that patients exhibiting xanthoma of the eyelids have a dark discoloration of the orbits, sometimes of a bluish or yellowish tint (xanthochromie).

A chemical analysis of the xanthomatous tissue made by Mays proved the presence of fat and fatty acids, but the absence of tyrosin and lecithin.

In regard to treatment, internal medication (arsenic, phosphorus, turpentine, etc.) is absolutely futile. Excision is recommended by the majority of authors, and is practised extensively. It is done with a pair of curved scissors followed by careful suturing of the wound with a very fine needle and silk. In cases of superficially located patches, this method of treatment is efficient; but if practised on large or deep-seated spots, it is liable to be followed by a disfiguring scar, or even ectropion or epiphera. It is also very difficult to remove all the affected tissue at once in this way, on account of its irregular extension into the deep layers of the integument.

The Paquelin cautery is not applicable by reason of its radiating heat. The galvanocautery, on account of the absence of radiating heat, is undoubtedly preferable to the Paquelin; but the destruction which is produced is too far reaching, and, therefore, somewhat beyond the control of the operator. The same may be said of caustics (nitric acid, carbolic acid, chloride of zinc, arsenical paste, etc.). Some authors have devised measures to safeguard the eye and the healthy skin against excessive cauterization by using a layer of thin metal or strips of adhesive plaster, exposing only the affected area.

Electrolysis has none of these disadvantages. It attacks the deposits of degenerated tissue in an elective manner, and its action is strictly local and at all times under perfect control. Furthermore, the pain connected with it is very moderate. The hydrates of calcium, potassium, and ammonium, which are formed on the negative pole (needle), combine with the fat of the xanthoma cells, forming a saponaceous material which partly escapes in the form of a lather at the point of entrance of the needle, partly remains in the tissues, with continuing destructive action. In order to reach the xanthoma deposits, it is necessary to introduce the needle horizontally with the skin, penetrating in the direction of the levator palpebrarum muscle.

In a previous communication, I called attention to the establishment of local anæsthesia produced by the galvanic current on the negative pole. This anæsthesia is, I believe, the same as that which is produced by the forcible endermatic injection (infiltration) of an inert liquid, for example, water, by aid of a hypodermic syringe. It is probably due to the formation of free hydrogen, which forces the liquids formed simultaneously with the hydrogen rapidly into the tissues. The intensity of this anæsthesia is in direct proportion to the voltage of the current. The voltage would, therefore, be equivalent to the pressure exercised upon the piston of the hypodermic syringe. A current of one-half milliampere and thirty volts will render a spot of the size of a pea anæsthetic in two or three minutes. After that the amperage of the current may be increased without causing pain. It is advisable to let an assistant manipulate the rheostat, while the patient touches the sponge electrode connected with the positive pole, and the operator introduces the needle connected with the negative pole. In this manner, the current can be started very gradually and increased without the production of unpleasant shocks. The hand of the milliameter should be brought back to zero in the same gradual manner. A current strength of two to three milliamperes is sufficient, but it must be continued for about thirty seconds. Some experience, however, is required in order to judge if the needle should or should not be left *in situ* for a somewhat longer period.

The electrode to be connected with the positive pole, advised by me some years ago, is very useful in this operation. It enables the patient to close or to open the current by simply closing or opening the hand, and, by more or less compressing the sponge of the electrode, to increase or to decrease the current strength independently of the operator. In order to introduce the needle in a horizontal direction as pointed out above, it is advisable to have the needle fixed at an angle of about forty-five degrees.

After the operation, there are sometimes œdematous, urticarial swellings, which, however, soon disappear. Patches more superficially located soon assume a dark greenish color, the deeper ones become brownish, or almost black. It is hardly possible to remove the somewhat larger spots at one sitting, but two or three sittings are usually sufficient. No dressing is required after the operation, except, perhaps, the application of a little dusting-powder, boric acid, oxide of zinc, or amylum. The patient should be directed not to rub or to wash the parts which have been treated. I have found that in this manner a considerable quantity of the caustic alkali, developed by electrolysis around the needle in the tissues, is left in place, and allowed to continue to exercise its destructive action. A firm adhering scab is formed as early as the second day. It is often surrounded by a slightly raised area of inflammation, which gives the spot an umbilicated appearance. In some cases, it takes rather a long time before the scab is dropped. After it has become detached, any remaining xanthomatous tissue is well exposed to view, exhibiting a strikingly bright yellow color. It seems that, by the inflammatory action produced after the first application, the deeper deposits are lifted toward the surface, where they are within easy reach for further electrolytic treatment.

741 Madison Avenue

The Treatment of Tetanus.—Rostevtzev has treated five cases of tetanus by the injection of an emulsion of calves' brain and spinal marrow, with four recoveries. Ehrlich has demonstrated that tetanic antitoxins are formed in the spinal cord, and Wassermann and Takaki confirmed his theory by their experiments, having prevented and arrested tetanus in animals by the injection of an emulsion of spinal marrow. Their explanation of the immunity obtained is that the injected substances circulate in the blood, and there combine with the free tetanic toxins and prevent their penetration into the cerebral centers. Four cures do not permit of definite conclusions; but in view of the difficulty there is in obtaining antitetanic serum, and the innocuousness of the injections of brain and marrow, with the possible benefit to be obtained therefrom, the author holds that this method may well be given a trial.—*Gazetta Medica di Roma.*

The Etiology of Tabes Dorsalis.—G M Holmes denies that tabes is a syphilitic disease, as the term is usually applied, because (1) The anatomical substratum has not the character of a syphilitic change; (2) Anti-syphilitic treatment is unanimously admitted to have little influence on the course of the disease, and may do positive harm; (3) Tabes generally occurs many years after syphilitic infection, and is seldom associated with true syphilitic processes; (4) Even the strongest supporters of the dependence of tabes on earlier syphilitic infection must admit that cases occur in which syphilis may be certainly excluded. Further may be mentioned the rarity of tabes among prostitutes, who have almost all had syphilis, and among people and tribes where syphilis is extremely common, as in Japan (Grimm), Bosnia (Gluck), and among the colored population of the United States (Burr, Trennen). He inclines to the compensation theory of Edinger. His explanation starts with the theory of Weigert and Roux that the various constituents of a tissue are in a state of equilibrium so correlated one to the other that no cell can disappear without the surrounding tissue growing to fill its place, and when one constituent becomes weaker or less resistant, the energy of growth of its neighbors represses it still further. But, should the proof of the accuracy of the Weigert-Edinger theory for the whole nervous system succeed, it is necessary that the possibility be proved that certain tracts under normal conditions are worked more than others, and that these tracts degenerate when stress, in the form of overwork, either relative or absolute, is associated with a disturbance of the general metabolism with deficient nutrition. There are undoubtedly a small number of nerves which are constantly or very frequently at work, or at least much more constantly in action, than any of the other nerves of the body. These are the sensory nerves from the muscles, which take an important part in the regulation of muscular contraction, and are constantly transmitting those stimuli by which we can become aware of the condition of our muscular system or the position of our limbs. These nerves are almost constantly at work, and if the hypothesis be right, these must suffer, and their degeneration is clinically expressed by loss of muscular tone and the deep reflexes, with ill-directed movements, without loss of motor power—ataxia. On similar grounds can be explained the sensory disturbances. These disturbances of sensation would naturally be found in the regions of the body where the nerves are most irritated by the pressure of the clothes or other means; and in tabes we find the scattered, and often irregular, patches of anæsthesia most constant on the soles of the feet or round the waist. The same explanation also suffices to account for the eye symptoms, symptoms referable to the bladder and rectum, etc.; in short, it will account for all the features peculiar to the disease. Hence, Edinger's theory, to the exploitation of which the whole paper is devoted, postulates the action of predisposing agents by which the nutrition or power of repair in the nervous system is affected; and, secondly, that on the soil suitably prepared by such noxious agents, function, normal or excessive, sows the symptom-complex.—*Dublin Journal of Medical Science.*

Hæmaturia in Childhood.—Campbell Williams says that it is often extremely difficult to decide as to the cause of the hemorrhage in these cases. Hæmaturia may depend upon purely local causes, or it may form but one symptom of some general systemic disorder. It is met in conjunction with rickets, infantile scurvy, and hæmophilia. Again, it occurs in connection with renal infarction, pneumonia, acute nephritis, typhus fever, variola, malaria, diphtheria, and scarlet fever. It is sometimes due to the presence of the bilharzia hæmatobia in the pelvis of the kidney or in the vesical veins. Another parasitic cause is the filaria sanguinis hominis, or it may result from the intravesical presence of migratory intestinal worms. Chlorate of potassium, turpentine, cantharides, and other drugs with definite action upon the kidney, or even heavy doses of boracic acid, may be provocative causes. Hæmaturia may result from traumatism of any portion of the uterine tract, or it may be due to the presence of a renal, ureteral, vesical or urethral calculus. It is likewise a symptom of tubercle or sarcoma of the kidney or bladder. The author gives details as to the differential diagnosis. —*Medical Press and Circular.*

The Hydriatic Management of Pneumonia.—David Paulson holds that the best way to combat the local congestion of the lung tissues is to produce a cutaneous hyperæmia in the blood vessels of the back, by prolonged application of heat to the back, alternating once an hour with cold applications, as this will increase the physiological action of the heat. At the same time, excellent results will be secured by applying, especially during the early stages of the disease, the cold compress or ice compress to the chest, exchanging it every hour or two for a hot fomentation to prevent the superficial tissues from becoming dangerously chilled from too prolonged application of intense cold. Cold to the chest causes contraction, not only of the surface blood vessels, but of the pulmonary vessels as well. The elimination of poisons will be encouraged by copious water drinking, by daily enemas and short sweating packs, or even short hot baths, when the patient is not too feeble. All hot applications should be supplemented by some brief cold treatment. The dietary should consist of well-dextrinized cereals and the easily digested fruits, rather than flesh foods, which must contain more or less of the waste products resulting from animal metabolism.—*The Medical Standard.*

Birdlime for Catching Rats and Mice.—S. Vernon Kay says that climate has everything to do with the variety of birdlime to be used. In England, or similar temperate climates, the birdlime's greatest adhesive powers should be active between 60° and 80°. The thick green "Cheshire" birdlime is found to be the most effective, but in hot weather it becomes rather thin. To make a colony of rats desert the burrows, it is only necessary to smear a little birdlime round the entrances. If it is desired to catch them, dress plenty of straws and spread them thickly on the ground near the burrows, throwing among them some attractive bait, such as malt sprinkled with oil of caraway. The next morning, the straws will be found gathered up into little bundles, in the center of each of which is a rat. The same method may be used in catching mice. Birdlime will not adhere to anything wet, therefore the hands and scissors should be kept in that state. The knife should be kept dry. If the birdlime is bought in tins, it should be warmed gently to thin it, then the lid may be removed, and the point of a dry knife dipped into the birdlime, drawing it out in ropes. These may be cut with wet scissors, and the birdlime smeared with the knife on whatever it is expected to cover.—*The Hospital.*

Beriberi and the Heart.—Arthur Stanley concludes that this disease has a marked degenerative action on the heart muscle, which frequently causes fatal circulatory failure, in this respect resembling other toxæmic diseases, such as diphtheria, influenza, alcohol, and arsenic poisoning, which often cause peripheral neuritis; and toxæmic diseases, such as typhoid fever, plague, and acute rheumatism, which do not, or rarely, give rise to peripheral neuritis. Beriberi and diphtheria are the diseases *par excellence* in which sudden heart failure occurs. The heart-muscle degeneration is not a secondary result of neuritis of the vagus. It takes place, as a rule, before skeletal-muscle degeneration, and is probably the result of direct action of the toxin. Sudden heart failure does not indicate a sudden lesion, but is the result of a gradually increasing heart weakness from myocardiac degeneration, which may be precipitated by any sudden exertion, but more frequently is the result of the principle of "all or nothing"—the transition from "all" to nothing being necessarily rapid. The cardiac physical signs in beriberi closely resemble those

found in diphtheria, and are of paramount importance in prognosis and treatment.—*The Journal of Tropical Medicine.*

History of a Peculiar Outbreak of Diphtheria.—Marshal O. Leighton states that from the 10th to the 23d of March, 1901, there appeared in the town of Montclair, N. J., twenty-one cases of diphtheria. The fact that they all occurred on one dairy route, the cessation of their occurrence two days after the quarantine of the dairy, and the existence of virulent diphtheria germs in the throats of milkers formed a chain of circumstantial evidence leaving no question as to the culpability of the milk. Moreover, during the same interval of time, there occurred on the route of this dairy in the city of Newark sixteen cases; in East Orange, ten cases; Orange, two cases; South Orange, two; West Orange, one; Verona, one; Passaic, two. There was also a case in New York City, the patient being stricken upon the day following that upon which he left Montclair, where he had been living in a family supplied with this milk. Again, in Caldwell, where the dairy is situated, and where no milk is delivered by this company, a case occurred in the family of an Italian cheesemaker, who bought all the skimmed milk from this dairy.

Richard Cole Newton, speaking of the same epidemic, calls attention to some of its more striking clinical features. What most excited his wonder was the average age of the patients, nearly all were adults, and the youngest patient was six years old. The course of the epidemic seems to have been mild. The human breath, as a vehicle of direct contagion, has not received the attention which its importance demands. Aside from the danger caused by coughing and sneezing and thus blowing particles of moisture from the mouth to the milk, the milkers probably talk and laugh together while milking; this source of danger should be carefully guarded against in the model dairy. A shield of gauze or wire could easily be interposed between the milker's mouth and the milk pail.—*Pediatrics.*

Treatment of Tuberculosis by Feeding.—Samuel Bernheim holds that mere stuffing of tuberculous patients is not wise treatment. They must be treated individually, and the dyspepsia so frequently accompanying the disease must be taken into consideration. Nitrogenous food has the property of repairing tissues, and is therefore valuable. Meat, especially beef and mutton, is to be recommended. It should not be highly seasoned, for tuberculous patients easily tire of condiments, which are also injurious to the digestive powers. It should be given raw. The experiments of Richet and Héricourt show that dogs, rendered tuberculous, die at about the fortieth day if they are not fed on raw meat; whereas, if this constitute their entire diet, they live about 240 days. Clinical facts bear out these experimental researches. Raw meat contains many toxic principles, animal alkaloids, ptomains, albumins, and extractives, which very probably possess an antitoxic property in regard to the bacillus and its toxins, or they may act merely as antidotes. Whatever the method of action, the practical conclusion is to feed consumptives on raw meat.—*L'Union Médicale du Canada.*

Cancer of the Genital Organs.—Attilio Faconti states that carcinoma of the genital organs occurs more frequently among poor women than among the well-to-do. Cancer of the left mammary gland in two-thirds of the cases is rare in nulliparæ, and occurs most frequently in women between forty and sixty years of age. Carcinoma of the vulva is found in 3 per cent. of the genital cases, and usually between sixty and seventy years. Vaginal carcinoma occurs in 33 per cent. of the genital cases, but is primary in only 2 per cent. Nine per cent. of the cases are found in nulliparæ. Uterine cancer is rare in nulliparæ, but is most frequent in those who have borne five or more children. The author does not believe that the generative functions have a direct influence on the production of carcinoma. Indirectly, the ignorance of hygiene of the race and neglect of inflammatory uterine affections in the poorer classes, may influence the development of a malignant growth.—*La Policlinica Medica.*

Minute Foreign Bodies Superficially Wounding the Eye.—A. C. Core emphasizes the statement that these superficial wounding particles (bits of steel, iron, cinders, rock, wood, sand, etc.) are often very hard to locate. He gives minute directions for the search which should be initiated by copiously washing out the cul-de-sac with collyria (boric acid, 15 gr. to the ounce, or tepid salt solution). Cocaine should then be instilled, the cul-de-sac above and below well turned out and inspected closely. The offending particle may be found sticking in the cornea, when the spud, or needle, or other sharp-pointed instrument, will have to be used. In the case of a piece of steel, the point of a clean magnet may possibly be successfully applied while the particle is being removed, the eye should be well irrigated with the syringeful of collyria; if the particle has been imbedded for some time, and especially if there is the least infiltration around it, the curette should be used, and a small amount of yellow oxide ointment (1 gr. to the drachm) carefully rubbed into it. Minute corneal wounds open the way for a variety of infections, hence the necessity for treating them with antiseptic precautions.—*The Medical Fortnightly.*

Cæsarean Section.—C. Everke, who has performed the operation sixty-four times with great success, urges its more frequent employment in routine practice. Perforation of the living child ought no longer to be performed. Under modern conditions, some institution where a section can safely be done is nearly always accessible, and the chances of the operation for the mother are as favorable as those of perforation, and the after-effects (peritoneal tears, fistulæ, etc.) much less to be feared. Antecedent examinations are not a contraindication, for energetic disinfection removes most of the germs, and vaginal injuries offer more chance of infection than does the laparotomy. The long median invision is to be preferred, while, to prevent hemorrhage and uterine atony, it is advisable to wait for the advent of labor pains before operating. Even in the most serious cases of eclampsia, mother and child may be saved by cæsarean section.—*Monatsschrift für Geburtshülfe und Gynækologie.*

The Treatment of Ecchinococcus Cysts of the Liver by the Baccelli Method.—A. Claps reports the case of a girl of eleven years, in which a diagnosis was made of echinococcus cysts of the liver. For four consecutive days aspiration was practised, fluid was removed, and washings were made with a 1 to 1000 solution of bichloride and a 1 to 100 salt solution. On the fourth day, the fluid was perfectly clear, and the operations were brought to an end. In all, 1000 grams of liquid were removed, the immense swelling of the epigastric region disappeared, and the volume of the liver was reduced. The patient made an excellent recovery, and a month later was found to be in good condition, well nourished, light hearted, and active.—*Giornale Medico del Regio Esercito.*

Notes on the Use of Tuberculin as an Aid to Surgical Diagnosis.—J. M. Elder concludes that tuberculin is valuable as a diagnostic aid in suspected lesions of glands, synovial sacs, and bones. In tuberculous peritonitis, in two cases tried, it gave no reaction. Its use was followed by no particular untoward symptoms, either local or constitutional. The reaction, as shown by rapid increase in temperature, varies in time, appears early in acute cases where the lesions are extensive, and should be looked for even as late as the end of thirty-six hours. The reaction does not appear to be constant, even when tuberculosis is undoubtedly present, but contra, in no case did the author obtain any reaction when tuberculosis, so far as could be determined otherwise, was not present.—*The Montreal Medical Journal.*

New York, December 7, 1901.

THE INFLUENCE OF MALARIAL INFECTION UPON CARCINOMA.

IN a short article by F. Loeffler, in *Deutsche medicinische Wochenschrift*, October 17, 1901, there is a discussion of considerable importance in connection with the pathology and possible treatment of carcinoma. The point involved is the effect of malarial infection upon the growth of the malignant neoplasm which we call carcinoma. It is very interesting to note that as early as 1775, a Polish observer, Truka de Krzowitz, wrote upon a case of mammary tumor, which is said to have disappeared under his observation some weeks after the supervention of a form of malarial fever. Although the growth in this case is said to have been cancer, modern observers would probably not accept this experience as very valuable, since the pathological data are necessarily defective, according to present-day ideas. However, it opens a line of investigation which is decidedly worth following.

Loeffler calls attention to certain facts which it is well to mention before discussing possibilities. It is hardly necessary to say that malaria is most frequent and most severe in the tropics, and that its frequency and severity diminish, in general, as we move away from the equator. It is also claimed, and the claim is believed to rest on sound statistical evidence, that carcinoma is practically unknown among the inhabitants of tropical regions, but that it increases in proportion as the temperate regions of the earth are reached. These facts may be admitted at once without conceding that there is an interdependent relation between absence of malaria and frequency of carcinoma, since it is the temperate regions which contain the largest proportion of human beings, and also the largest proportion of those who are designated civilized, upon whom all the other alleged causative factors of carcinoma are continuously at work. Mode of life in the tropics is so different from what it is in the temperate zones that much direct evidence would be required to show that malaria either prevented carcinoma or interfered with its cellular metabolism, and we might have to admit, after all, that the evidence collected supported the theory that carcinoma is a disease due to some deleterious effect of modern civilization and mode of life upon the most vital activities of epithelial growth and development. In this connection, what is most needed is a collection of trustworthy clinical observations, and physicians who live in the tropics and sub-tropics are those who can most rapidly accumulate experiences from which to support theories.

The action of the micrococcus of erysipelas upon some forms of sarcoma is analogous to the effect which malarial infection is said to have upon carcinoma by those who are willing to concede a certain amount of reason to the theory which we are considering, but in experimenting with erysipelas, the danger of serious or fatal consequences from the inoculation is always present, and has to a great extent discouraged experiment. In those cases of sarcoma in which erysipelatous inoculation has seemed to have caused disintegration and disappearance of the growth—and there are some such cases—the action is brought about by certain toxins, elaborated by the vital processes of the infecting bacteria, and by them sent into the circulating fluids of the inoculated individual. These substances then exert an unfavorable action upon the perverted cellular growth of the neoplasm, and eventually cause it to break down and undergo absorption. Of course, the nature of the malarial organism is different from any form of bacterial life, but it is reasonable to infer that whatever special action it has upon normal or perverted cell growth is brought about, not by the organism itself, but by the toxic substances to which its vital processes give rise. Indeed, the effect of malarial toxæmia upon the cells of the liver and kidneys is so well known as scarcely to need comment. Why the toxins of malaria should show a predilection for attacking the neoplastic cells of a carcinomatous growth, or why such cells should be specially influenced, we are unable to say; but we know in a general way that, although these cells show great activity and power of proliferation, their power of resistance is, under some circumstances, small, for many specimens of carcinoma show extensive and disseminated areas of cellular degeneration upon microscopic examination. It is not improbable that there is no specific action of the malarial toxins upon the carcinoma cells, and that any effect upon them is due to their inability in a marked degree to resist unfavorable influences.

We must look to experimental research to throw light upon this interesting and important question, so that we may, if possible, have some means of treating the most dreaded of all diseases, other than what is offered by early diagnosis and radical surgical operation. Gerhard and many Italian observers have shown that it is possible to inoculate a healthy individual with malaria from the blood of one who has malaria, and having quinine in our possession, we need not fear that this disease will become uncontrollable. Nothing but experimental observation and study of the life activities of the plasmodium can ever give us the knowledge of how to pursue such inoculation experiments rationally, accurately, and with a reasonable prospect of uniform results; but we need not fear that we shall lack subjects for experiment, for there are very few victims of carcinoma who would refuse to risk a malarial infection, if any prospect of benefit could be held out to them. To prove anything, a large number of observations would have to be made, and the statistics of neoplasms of all kinds from notoriously malarial regions, especially those in the more temperate parts of the earth, would have to be collected. A series of inoculation experiments with the blood-serum of a victim of malaria upon a patient with carcinoma would be interesting and might lead to valuable results.

TYPHOID FEVER AMONG SOLDIERS

A BOOK recently published by Dr. Leigh Canney, entitled "Typhoid, the Destroyer of Armies, and Its Abolition," has been the occasion of no small amount of discussion. There are several reasons for the extreme interest which has been taken in the book, not the least being that it is exceedingly well written, and that although the writer's views as to the causes of the disease differ in degree from those of most authorities, he nevertheless suggests means apparently practicable for preventing its outbreak and for checking its spread.

Enteric fever in all the wars ever waged has probably killed more men than sword or bullet, and any measures whereby its ravages might be appreciably controlled would be gladly welcomed.

Dr. Canney is a firm believer in the theory that polluted water is the predominant cause of typhoid fever; in fact, he goes so far as to attribute but little weight to the opinion of those observers who hold that there are other vehicles of infection which, in the origin and spread of the disease, must be taken into account. He looks upon the matter as simply a question of pure or impure water.

It has been remarked many times in the RECORD that while fully agreeing with the majority of investigators, that water is the chief agent in the causation and dissemination of typhoid, yet there are strong reasons to believe that flies and dust play an important rôle in spreading infection. The results of the enquiries made in the military camps of this country, during the Spanish-American War, by Dr. Victor Vaughan and others, and embodied in their report, as well as the outcome of investigations carried on in South Africa and elsewhere, leave little room for doubt that such is the case.

However, it is certain that the assuring of an uncontaminated water supply would lessen, to a most remarkable extent, the danger to soldiers in the field of becoming infected with the poison of typhoid.

Thus recommendations tending to effect this object, and which seem to promise any hope of success, should be received with gratitude, and discussed thoroughly by practical men before being rejected as chimerical or Utopian.

Dr. Canney suggests that, in order to ensure a pure water supply for soldiers on the march, a "water corps" should be formed, with duties somewhat as follows: Two men of this corps would be attached to every unit of 100 men, and in charge of a mule able to carry two appliances for boiling water, with apparatus for cooling, petroleum for fuel, the allowance for each man to be, if required, as much as four pints a day; the water-mules to take precedence of all transport except ammunition, while the troops would be instructed to drink no water that had not been boiled.

Difficulties undoubtedly there are in the way of bringing such a scheme to successful issue, but at the same time it would appear to possess numerous good points. Any plan—not wholly impracticable—which will tend to decrease the fearful scourge of typhoid fever among troops on the march is at least worthy of consideration.

Dr. Smith Ely Jelliffe has been appointed visiting neurologist to the City (Charity) Hospital, N. Y.

COMMERCIALISM IN THE MEDICAL PROFESSION.

THE charge has been frequently brought, of late, against the profession that it is becoming, to some extent, imbued with a too great love of money-making, and that business instincts are overcoming the honorable traditions, with regard to the practice of medicine, handed down by physicians of the past. Doctors have ever borne the name of being among the most charitable and self-abnegating of men, whose integrity has been beyond cavil. Of course, there have been black sheep within their ranks, but, taken as a class, the dignity of the calling has been splendidly upheld.

Therefore, when from many quarters it is proclaimed that some are deviating from the line of conduct enjoined upon them by their forerunners, both by example and precept, it would seem that a slur, unmerited or otherwise, has been cast upon the entire medical profession.

Dr. John R. Roberts read before the Philadelphia County Medical Society recently a paper which is the most severe indictment yet made of certain of the present-day methods which obtain in the practice of medicine. He lays bare the various means adopted by tradesmen to undermine the principles of the doctor, he inveighs against the advertising dodges of all sorts and kinds which are made use of to lure him from the paths of virtue, and he breaks a lance with the life insurance companies, and asserts that they have a code quite unlike that which the true profession believes to be honorable. In fact, Dr. Roberts makes war upon all practices which he deems unworthy or detrimental to the best interests and honor of the medical profession.

Especially is he severe on the custom—said to have developed of late—of dividing fees, and declares that a large number of consultants are sadly lacking the milk of human kindness.

He is of the opinion that the triumphs of modern medicine and surgery have turned the heads of some practitioners, and that charges have been so large in certain instances as to be properly dubbed extortionate.

Much of this is undoubtedly true, and it may be that the medical profession has grown somewhat lax, as regards strictly ethical conduct. Many things done by some medical men nowadays are greatly to be reprobated, and perhaps a belief in the "omnipotency of gold" has debauched the professional spirit of these times; but, on the other hand, as Dr. Roberts himself allows, possibly "the doctors only breathe the same air and react to the same environment as their business associates."

While it does no good to play the part of a Don Quixote, and to tilt against windmills, yet it is only right and proper to protest vigorously against the infringement of those laws, written and unwritten, which have for so long regulated the conduct of the medical profession.

This is a matter which intimately concerns doctors, both individually and collectively, and it must be left to them and their governing bodies to sweep away abuses, and to keep the profession as free as is possible from this subtle, dangerous, and pervasive taint of commercialism.

CAMPAIGN AGAINST MOSQUITOS IN WEST AFRICA.

A very vigorous campaign—undertaken at the initiative of Major Ronald Ross and under the auspices of the Liverpool Tropical School of Medicine—is being waged against the pestilent mosquito in West Africa. The work was begun under the immediate supervision of Major Ross, who has now returned to England, and is being conducted at the present time by able lieutenants.

On October 21, Major Ross gave a lecture in Liverpool, in which he told of some of the steps being taken to relieve, as far as is possible, the West Coast from the menace and discomfort of the malaria-bearing mosquito. It seems that the British Governors and officials generally, in that part of the world, are loyally co-operating to render this experiment a success; and every known means is being brought into play for the extirpation of the pernicious insect. The breeding pools when found are drained, and larvæ destroyed by oil. Quinine is also universally used, the white population segregated, and entrances and windows of houses protected by wire-gauze screens. It is interesting to notice that, contrary to common report, Major Ross declares that he does not believe it possible entirely to eradicate mosquitos, but thinks it quite feasible greatly to reduce their numbers in towns by abolishing their breeding places. If this much can be accomplished, the life of Europeans who live in tropical countries where mosquitos abound will be rendered more endurable.

YELLOW FEVER STAMPED OUT IN HAVANA.

A report from Major W. C. Gorgas, Surgeon United States Army, chief sanitary officer of Havana, just received by Surgeon-General Sternberg, shows a great improvement in the sanitary condition of that city. This is particularly noticeable with reference to yellow fever, not a case of which occurred in Havana during the month of October, usually the period of the greatest prevalence of the disease. For the past ten years the average number of deaths in Havana from yellow fever during the month of October was 60.27. In October of 1896 there were 240 deaths from this disease, and 25 in 1899, the lowest previous rate in the past decade. In October, 1900, there were 308 cases, with 74 deaths. During the same month of the present year there were no cases of yellow fever and no deaths from this cause.

In his report Major Gorgas says: "The great truth that yellow fever is transmitted by the stegomyia mosquito, maintained by Dr. Charles Finlay against much ridicule for so many years and recently demonstrated by the army board, must soon change our methods of quarantine in the United States. In Havana, this year, we have worked upon the hypothesis that the mosquito is the only way of transmitting the disease. We have not considered fomites in any way. Clothing has not been disinfected, nor any effort made except to kill the mosquitos which had bitten a sick person and to prevent any more mosquitos from biting, after the case was discovered. Our results with this plan were so positive that we soon saw that we could not only rid Havana of yellow fever on these lines, but that we could destroy each focus as it was removed from the outside. . . .

The practical application of this great truth, made in Havana this year, will, within a few years, it seems to me, be carried out by our Southern cities liable to yellow fever. It seems to me that if, in Havana, where yellow fever has been epidemic for 150 years, and where at present there is a non-immune population of something like 40,000 people, we cannot only get rid of yellow fever, but have free communication with half a dozen infected towns in our neighborhood, and yet prevent the introduction of the disease, then all our Southern cities ought more easily to do the same thing.

"The general health of the city is most excellent, better than that of any past October, and compares favorably with healthy cities of civilized communities. The death rate from month to month shows steady improvement, indicating generally improved conditions."

MORTALITY IN THE CONCENTRATION CAMPS OF SOUTH AFRICA.

The death rate of these camps has given rise to somewhat harsh criticism of the policy of the British Government in establishing the same, and of its assumed neglect in not keeping them in a good sanitary condition. The mortality is stated to be excessively high; indeed, among children, if accounts be true, appalling.

The *London Daily News*, a journal of pro-Boer sympathies, gives a most ghastly description of the state of the camps, and the British public seem inclined to take up the matter and to insist upon a thorough investigation.

Manifestly, the question as to how to dispose of the Boer women and children, during the progress of the war, is a most difficult one for the British authorities successfully to solve; but certainly every effort should be made to render these camps as healthful places of abode as circumstances will allow.

THE ALBANY FILTRATION PLANT AND THE DEATH RATE.

There are in this country many prominent examples of the good effects following the installation of filtration plants, and the consequent purifying of the water supply, none of which can show better results than that at Albany.

Wherever the slow sand filtration of water has been adopted, the mortality from typhoid fever has been greatly reduced, in some instances to an almost incredible degree. Mechanical filters are cheaper as to cost, but so far as public health is concerned, there is no comparison between the two methods.

In Lawrence, Mass., before filtration was established, the average number of deaths from typhoid fever was 52 per annum; after filtration, 13.8 per annum, a reduction of 75 per cent. In Ashland, Wis., before filtration, average number of deaths from typhoid fever was 39 per annum; after filtration, 4.5, a reduction of 88.5 per cent.

In Macon, Ga., before mechanical filters were established, deaths from typhoid fever totaled 10.5 per annum; after filtration, 7 per annum, a reduction of 33 per cent. In Oakland, California, before mechanical filtration, deaths from typhoid, 19; after filtration, 17, a reduction of 11 per cent.

A comparison of the average number of deaths per year in Albany for the year 1900 with that of the average for the decade previous to the installation of the sand-filtration plant yields the following results: The average number of deaths for the ten years immediately preceding 1900 had been 2,186 per year; the number of deaths for the year 1900, during which filtration was in operation, was 1,742, a decrease of 444 deaths.

The year 1900 was distinguished throughout New York State by the high mortality rate, so that the figures from Albany have a special significance.

Regarded from the point of view of typhoid fever

alone, the Albany plant has shown itself a most important factor in the decrease of that disease. The deaths from typhoid fever per year for the decade up to the installation of the filtration plant had been 84, while in 1900 the number of deaths from the same cause amounted to but 39.

Sand filtration in every city or town in which it has been given a trial has largely reduced mortality, and the method is undoubtedly the greatest safeguard against typhoid fever that has been introduced.

The citizens of New York would appreciate the establishment of a system which has plainly demonstrated its efficiency in practically banishing the scourge of typhoid fever.

The Modern Corset and Visceral Ptosis.

Grave charges have been on several occasions brought against the corset as being the cause of much discomfort, and not infrequently of serious complaints, among the female sex.

Dr. Agnes Victor, assistant surgeon to the New England Hospital, Boston, has recently advanced yet another indictment against the modern corset, and asserts that it is an important factor in visceral ptosis.

Dr. Victor supports her contention with numerous instances drawn from her own experience, and proves, in a more or less convincing manner, that the modern corset is really often mainly responsible for the condition referred to in women.

There is no doubt that a tightly laced, ill-fitting corset, although it may have the desired effect of shaping the female frame in consonance with the prevailing fashion, is ofttimes not only an instrument of torture, but the *fons et origo* of many dire diseases.

Dr. Victor would seem to favor what is known as rational dress for women, and advises a corset for visceral support constructed as follows: "A straight front made of several sections, running from below obliquely upward and backward; hip gores; back gores; fit the abdomen first, and from below upward; then fit the chest; leave the waist in its place. Especially should patients be warned that it is not enough to have a straight front; they must also have room in the back for an oblique pelvis." Dr. Victor is an advocate for a radical change in the mode of women's dress, and believes with Abernethy that the less lacing the better will it be for the health of the weaker sex.

This is doubtless the correct attitude with regard to the question; but it is to be feared that the time is not yet ripe for so revolutionary an alteration in woman's dress as suggested by Dr. Victor. Fashion still exercises such a potent sway over the minds of the majority of women that they will undergo manifold discomforts and injuries rather than look dowdy or unstylish.

Rats and the Plague.

From the time when plague was first known, rats have been thought to be intimately connected with the disease, and to be one of the most fruitful means of dissemination. Latterly, this belief has become so strong that it would seem to have almost passed from the region of conjecture to that of established fact. That rats suffer from plague has been verified with certainty, although the exact connection between the malady as affecting man and as affecting rats has not been determined.

Major Deane, R.A.M.C., special plague medical officer, Calcutta, according to the *Indian Medical Gazette*, in a report recently made by him, has absolutely denied that rat plague can be transmitted to man, and says that "rats have practically no concern with plague."

With all due respect to Major Deane's experience and knowledge, the history of former epidemics of plague is altogether against this view of the case. It must be something more than a coincidence that, in nearly every outbreak of plague among men, there has been beforehand either an epidemic among rats, or the disease in both species has been discovered at the same time.

True, clear evidence is lacking to show that rat and human plagues are intercommunicable, the most plausible theory in favor of this supposition being that the flea acts as intermediary, advanced by Simond and supported by Ashburton Thompson and others. Major Deane's attempted refutation of the long-held belief that rats play a part in the propagation and spread of plague is original, but he must adduce further and more convincing proofs before his statement will be generally accepted.

Sumptuary Legislation Again.

Elated by the success which, during the last session of Congress, attended their efforts to legislate out of existence the army canteen, an institution created for the temperance, discipline, and comfort of the soldier, the prohibitionist element now proposes to go still further and make it a military offence for the soldier to indulge in a glass of wine or beer, or to refuse to partake of the literary pabulum which these gentlemen propose shall be furnished to the army. A draft of a proposed law to this end, having the endorsement, among others, of President Jordan of Stanford University, is now being circulated among Congressmen by the Anti-saloon League of Berkeley, Cal.

The draft of the proposed measure is as follows:

"An act prohibiting the use of intoxicating liquors and opium in the military service, and providing libraries, reading-rooms, and schools for the military and naval forces of the United States.

"*Section One.* No person who is addicted to the use of intoxicating liquors or opium shall be enlisted into the military service of the United States.

"*Section Two.* No person during the term of his enlistment in the military service of the United States shall use intoxicating liquors or opium except upon the prescription of a physician or surgeon.

"*Section Three.* Libraries, reading-rooms, and schools for enlisted men, with compulsory attendance thereto, shall be established throughout the army and navy of the United States.

"*Section Four.* The secretaries of war and navy are hereby directed to carry the provisions of this law into full force and effect."

The provisions of this bill illustrate the intolerance of the sentimentalists through whose efforts the army canteen was abolished, and at the same time show their complete ignorance of the military matters upon which they presume to pass judgment.

The requirement laid down in Section One is totally unnecessary, as War Department instructions have for many years expressly forbidden the enlistment of the class of persons mentioned therein, recruiting officers being cautioned to use due diligence in this respect. With respect to Section Three, libraries and reading-rooms have long existed in army posts, and are patronized freely by the men, all of whom, on enlistment, are required to be able to read and write the English language with ease and clearness. As to Section Two, to make the drinking of a glass of beer a punishable offence is an insult to the intelligence and character of the soldier, who, like any other citizen, has his rights and does not desire or need to be made the victim of sumptuary laws devised by a handful of irresponsible and

unreasoning zealots. Such bills as the one above mentioned excite the surprise, contempt, and disgust of the fair-minded and do much to bring the whole question of temperance into disrepute.

Institute of Medical Research Founded in the Malay Peninsula.

Circulars recently sent out by the British Resident General at Selangor, Federated Malay States, calls attention to the institute for medical research recently established by the government of those states. The institute is situated in Kuala Lumpur, the capital of the Federated Malay States and is open to all workers irrespective of nationality. The medical department is stated to be fully equipped for special and general pathological work, for the scientific study of clinical medicine, experimental physiology and bacteriology. A modern mortuary with a refrigerator chamber is a feature of this department. A department of chemistry is equipped for both organic and inorganic research. There is, in addition, a well-equipped photographic department, facilities for biological research, and a good working library.

The circular states that the institute and its resources are open to all, irrespective of nationality, under the conditions that usually obtain in such establishments. To the members of scientific commissions who visit the Malay Peninsula and neighboring islands, the institute affords excellent facilities for working up and preparing collected material. To students of tropical medicine the field for work is large. Beriberi, especially, exists under unique conditions. Malaria is found in at least four distinct types. The institute is at present under the direction of Hamilton Wright, M.D., a graduate of McGill University, Canada, and any communications addressed to him with reference to the Institute will be welcome.

The Decreased Birth Rate in France.

The gradual but steady and progressive decline in the population of France has long excited feelings of distrust and concern among all thoughtful people. Not only is the birthrate smaller than in almost any European land, but the infant mortality is also extremely high. This state of affairs has been recently recognized by the government as one to which attention must be paid, and steps be taken to provide, if possible, remedies to combat the evil. According to the New York *Sun*, November 24, a debate on the subject took place in the Senate on November 23, when the Premier, M. Waldeck-Rousseau, accepted in the name of the government a proposal for the nomination of an extra parliamentary commission, to seek means of increasing the birth rate and diminishing mortality.

That France has failed to keep pace in point of population with the other large nations of Europe will be clearly evident when it is stated that, at the commencement of the nineteenth century, France had 26,000,000 inhabitants, Germany 15,000,000 inhabitants, and England 12,000,000 inhabitants. Now France has 38,000,000 inhabitants, Germany 56,000,000, and England 41,000,000.

The remedies recommended by one Senator were the adoption of fiscal measures in favor of large families, and, above all, of legislation to check the terrible mortality among infants.

The high death rate among infants is largely attributed to the pernicious habit of baby farming which prevails among the rich and upper middle classes of France, while probably one of the causes of the low birth rate is the fact that a large number of the French people are too penurious to desire the expense of raising a large family. France, however, has now come to the conclusion that such a system is in the long run one of false economy.

Compliment to the Medical Department of the Army.

A report has just been received at the War Department from Capt. J. S. Kulp, assistant surgeon, U. S. A., in regard to the hospital and sanitary service of the British Army, and his conclusions are flattering in regard not only to our own medical department, but to the American soldier. On the whole, he thinks that the Medical Department of the United States Army has little to learn from Great Britain. He says that the British recruits compare unfavorably with our own, largely due to the poor pay of the British private, about 28 cents a day, which keeps them in a condition of practical poverty. He says: "The undersized, underfed and undeveloped boys one sees in the English ranks or invalided from South Africa are not at all representative of the sturdy English race. Our own recruits, even among our volunteers, are mentally as well as physically superior to them, and our instruction very properly begins at a more advanced point. In concluding his report, Capt. Kulp says: "South Africa has taught England what it is hoped we have learned during our late war, namely, the value of an organized medical department possessing real authority in relation to all subjects affecting the health of troops."

Wound of the Heart—Recovery After Suture.

Watten, in *Deutsche med. Wochensch.*, September 12, 1901, adds to those already reported a case of stab-wound of the heart and pleura which was operated upon. A thoraco-plastic operation was done, and the wound in the right heart closed with two sutures after some difficulty. A point of interest is that the operator was compelled to introduce his hand into the pericardial sac behind the heart and thus to steady it while the sutures were being introduced and tied. It is said that the heart's action became much less tumultuous and of a better character as soon as the wound in it was closed. The pneumothorax disappeared after a time, and the patient made a complete recovery. The case well illustrates how much handling the heart will endure and still do its work. All the wounds in skin, pericardium, and pleura were closed practically, completely, a method of handling which seems to be necessary in cases of this kind. Asepsis is, of course, of pre-eminent importance.

What Overwork Means.

Professor Huxley gave his opinion in 1893 that what is called overwork means, in a large proportion of cases, under-oxygenation, and consequent accumulation of waste matter, which operates as a poison. Sir J. Sawyer Birmingham, in corroboration of this opinion, urges that much chronic invalidism is chronic suboxidation, and one of the worst of wrong conditions is work in stale air. Whenever we doubt about our vitality, we should doubt about our ventilation. Dr. Cheadle reminds us that one-third of our lives is spent in our bedrooms, of which the air is poisoned, beyond what would be tolerated in a sitting room. It is well conceded that many of the cases of nervous disease, and especially the various forms of neurasthenia, depend largely upon want of open-air exercise.

News of the Week.

A Very Willing Witness.—A man who represents himself to be from some "Press Association" is now calling on physicians claiming to have some information concerning the practice of "Osteopathy" which would be of the greatest value to the medical profession. He, of course, designates the practice as a gigantic fraud and an imposition, and a menace to the public health. He offers to sell this evidence, and, failing in this, wishes moral support in his self-imposed missionary work. He asks for signatures to a petition of some kind, and solicits subscriptions, using the names of different prominent men, that of Dr. Van Fleet among the rest. Physicians should be careful in signing any petitions which he may present, or in making subscriptions until they are certain the cause is a worthy one, and the person representing it is authorized by some organization or person other than himself to represent it.

Barring Out Consumptive Immigrants.—The case of the man, Thomas Boden, whom the United States Treasury officials ordered to be taken back to Ireland, because he had tuberculosis, which they held to be a "loathesome or dangerous disease," and consequently a bar to his admission to this country, was passed upon last week in Brooklyn. Judge Edward B. Thomas decided in favor of the ruling of the Treasury Department, and unless the case is appealed, the man will be deported on Saturday. His wife and child will return with him. He arrived here on November 9. Physicians examined him on his arrival, and when they reached the decision that he was suffering from tuberculosis, he was sent as a temporary patient to the Long Island College Hospital. The Treasury Department, on special appeal, ordered another examination, and the original diagnosis was confirmed. It was then ordered that he be deported, but relatives took the case to the United States Court for decision.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy for week ending November 30, 1901. November 22—Asst. Surgeon J. J. Snyder, ordered home and granted three months sick leave. Asst. Surgeon Edgar Thompson, detached from the Naval Hospital, Chelsea, Mass., and to duty at the Charleston Exposition in charge of the exhibit of the Medical Department of the Navy, and in attendance on the Marine Guard, and the Marine Recruiting Rendezvous. Medical Director R. C. Persons, commissioned Medical Director from November 3, 1901. Medical Inspector E. H. Green, commissioned Medical Inspector from November 3, 1901. November 25—Surgeon N. H. Drake, detached from duty as member of the Medical Examining Board, Naval Laboratory, New York, and ordered home to wait orders. Surgeon A. C. H. Russell, ordered to duty as member of the Medical Examining Board, Naval Laboratory, New York, December 4. November 26—Asst. Surgeon D. G. Beebe, resignation accepted to take effect November 30, 1901. November 27—Asst. Surgeon Edgar Thompson, commissioned a P. A. Surgeon from April 19, 1901. Dr. J. B. Buchanan, appointed an Assistant Surgeon in the Navy from November 23, 1901.

The Cause of the St. Louis Tetanus Outbreak.—The commission appointed to investigate the cases of tetanus following the administration of diphtheria antitoxin in St. Louis has concluded its labors and made a report, which is published in the *St. Louis Medical Review* of November 23, 1901. The members of the commission were Drs. B. Meade Bolton, C. Fisch, and E. C. Walden, and their report is a very serious arraignment of the methods of the city Health Department by which the poisonous antitoxin was prepared.

The following are the conclusions of the report.

"As a result of our investigations we draw the following conclusions: The diphtheria antitoxin prepared by the Health Department of the City of St. Louis, and dated September 30 and some of the serum dated August 24, was the cause of the recent deaths from tetanus in the cases where diphtheria was used. This antitoxin was sterile, but contained the toxin of the tetanus bacillus in considerable amount.

"There were two different sera issued under the date of August 24. One portion not containing the tetanus toxin and characterized by other properties, while the other contained the tetanus and was identical with the serum bearing the date of September 30.

"The most important result we have arrived at is the positive demonstration that the toxic serum dated August 24 and that dated September 30 are identical. From this we conclude that the serum of September 30 was issued without having been tested by the proper methods, and that a part of it was filled into bottles bearing the date of August 24, and were furnished with labels having previously been stamped with this date. We are justified in drawing this conclusion from two observations. First, that the serum of September 30 was issued before there was time to have performed the simple tests necessary to determine the antitoxic potency of the serum. Second, in the same way, serum, dated October 23, came into our possession on November 1. This serum had been issued to physicians by the Health Department and by them returned to the coroner. It is obvious from this that no animal experiments could have been made with this antitoxin. As this was the case with the serum of October 23, it is the natural inference that the serum of September 30 was issued in the same way.

"We must deny any possibility of latent tetanus having existed in the horse 'Jim' from August 24 to September 30, as no well-authenticated cases have been reported in which the incubation period extended over seven days, in experiments directed to test this point. The period of incubation cannot be determined from clinical observation, from the nature of the case. It therefore follows from this that the serum drawn on August 24 was free from tetanus, but that the serum of September 30 was drawn during the period of incubation, and had it been tested upon animals it must necessarily have revealed its toxic properties.

"From the foregoing facts we are forced to conclude that the diphtheria antitoxin prepared by the city Health Department has been issued before it was possible to have obtained results from the absolutely necessary tests. Had these tests been performed, the results upon animals would have been such that the serum would not have been dispensed, and the cases of tetanus forming the basis of this report could not have resulted."

The Death of Sir William MacCormac of London.—Sir William MacCormac, Bart., President of the Royal College of Surgeons, died suddenly on Wednesday, December 4, of heart disease, at Bath, England, aged sixty-five years. This sad announcement reaches us by cable as we go to press.

The Reappointment of William K. Van Reypen, Surgeon-General of the Navy.—President Roosevelt has decided to reappoint Rear Admiral Van Reypen upon the expiration of his present term on December 18, giving him the benefit of his age limit, and thus postponing for the time being the promotion of Medical Inspector P. M. Rixey, the physician of Mrs. McKinley.

Tuberculosis in Cleveland.—An investigation into the health conditions of the city, recently conducted by the public authorities of Cleveland, Ohio, has excited some alarm, and has led to a determination to enforce more strictly the existing ordinance prohibiting expectoration in the street cars. This investigation revealed the fact that tuberculosis prevails to an unusual extent, about one in every fifty of the inhabitants being a sufferer from that disease.

Smallpox in London.—The present outbreak of variola in London, which began six months ago, is credited up to the first of December with 349 cases and 116 deaths. The mortality among the unvaccinated has been 60 per cent., but among those whose arms showed one or more vaccination scars, the mortality was but 20 per cent. The number of cases is steadily increasing, and the authorities appear to have little hope of repressing the outbreak until the winter is past.

Surgical Work of the Army Medical Department in the Philippines.—Recent reports received at Washington give an excellent idea of the character and magnitude of the surgical work being performed by army medical officers in the Philippines For instance, at the First Reserve Hospital, in Manila, from July 1, 1901, until the date the report was mailed, there had been performed 120 major operations, besides many minor surgical operations, without a death. This record includes 16 operations for appendicitis, 3 for large aneurysms, 8 for large liver abscesses, and 24 for the radical cure of hernia. As good surgical results are being obtained in the army service in the Philippines as in the most modern civil hospitals in the United States, while the experience with certain classes of cases which can be obtained in the larger army hospitals is greater than that afforded by even the largest civil institutions in this country.

Twenty-four Hundred Hospital Corps Men are soon to be discharged from among those serving in the Philippines by reason of expiration of enlistment. To meet this contingency, General Chaffee has asked that 300 Hospital Corps men be sent from the United States to the Philippines in December, and that 110 be sent monthly, for a period of six months, after the embarkation of the first detachment. No difficulty is anticipated by the Medical Department of the Army in filling this requisition, even though it is of unusual size.

To Prevent Tuberculosis Among Troops in the Philippines. An order has recently been issued from headquarters of the division of the Philippines prohibiting spitting on the floors or walls of officers, barracks, and other buildings under control of the military authorities. Infringement of this rule thus becomes a military offence and punishable as such. This action was taken upon the recommendation of the Chief Surgeon of the division, that officer declaring that tuberculosis is both a contagious and an infectious disease.

Clinical Lectures in Orthopedic Surgery.—It is announced that Dr. Russell A Hibbs will give a course of lectures on orthopedic surgery at the New York Orthopedic Dispensary and Hospital, on Monday and Thursday afternoons of each week during December. The course is free to students and practitioners of medicine.

An International Federation of Nurses.—At a dinner given recently in London to the returned delegates to the Nurses' Congress held in the autumn in Buffalo, a proposal was made for the foundation of a confederation of British and American nurses.

Cause of the Tetanus Outbreak in Camden.—The Board of Health of Camden, N. J., has published a report of the investigation made to determine the cause of the tetanus which followed vaccination in several instances. According to this report, the outbreak of tetanus is "to be explained by the atmospheric and telluric conditions which have prevailed in Camden during the past six weeks. There has been a long period of dry weather with high winds, so that tetanus germs, which have their normal habitat in the earth, dust, dirt of stables, etc., have been constantly distributed in the atmosphere. It is noticeable in all the cases, after careful examination as to the cause, that the wound had been exposed by the scab being knocked off or removed, or else the arm had been injured and infection resulted; frequently children scratched the vaccinated arm with their dirty finger nails and infected the wound. It is the unanimous opinion of the Board of Health, as well as of its committee of experts, that vaccination should be insisted upon by physicians as an absolutely safe procedure for the prevention of smallpox. Tetanus or any other infection can never occur if the vaccination is properly protected from contact with the atmosphere or with soiled clothing or bandages."

An Insurance Swindle.—A man who claims to be an agent of the Michigan Mutual Life Insurance Company of Detroit is traveling through West Virginia and Ohio, swindling physicians. His plan of operating is to call upon a physician and tender him an appointment as medical examiner for the company on condition that the victim takes out a policy of insurance for $1,000, or whatever sum may be desired. The agent takes part of the premium in advance, assuring the physician that the examination fees will more than cover all future premiums. That is the last heard of the agent or the application for insurance. It may be well for physicians to remember that insurance agents do not appoint the medical examiners, and any one offering that bait for an application, especially if he asks for payment of any portion of the premium in advance, is in all probability a fraud.

The Military Tract Medical Association of Illinois.—At the annual meeting of this society, held at Macomb, the following officers were elected to serve for the coming year: *President*, R. A. Kerr of Peoria; *First Vice-President*, G. E. Luster of Galesburg; *Second Vice-President*, J. E. Coleman of Canton; *Secretary and Treasurer*, C. B. Horrell of Galesburg.

The Southern Colorado Medical Association.—At the first annual meeting of this newly organized society, held at Cañon City, on November 12 and 13, the following officers were elected: *President*, William A. Campbell of Colorado Springs; *First Vice-President*, Robert J. Pease of Cañon City; *Second Vice-President*, Benjamin F. Cunningham of Cripple Creek; *Secretary*, Cyrus F. Taylor of Pueblo; *Treasurer*, J. A. Blunt of Pueblo.

The Plague.—A report is published to the effect that a St. Louis man has received a letter from a friend in Honolulu, in which it is asserted that plague is making headway in that place, seventy-three cases being known to the authorities at the time the letter was written. A detention camp has been established at Kalihi, which is guarded day and night by armed men. The Honolulu papers do not publish any particulars concerning the disease. The only sufferers at present, according to this report, are Japanese and Chinese, fourteen of the former and nine of the latter.

Suits Against the St. Louis Health Department.—It is stated that the parents of several of the children who died of tetanus following injections of contaminated diphtheria antitoxin have threatened to bring suit against the city for damages. The

coroner's verdict, in which [illegible] were said to have been chargeable to the negligence of the Board of Health officials who manufactured the antitoxin, is made the basis for these suits.

Association of Military Surgeons.—Much interest is being shown by medical officers of the military service, and ex-medical officers of the volunteer forces, in the next Convention of the Association of Military Surgeons, which will be held in Washington, D. C., in June next. Since the recent adoption of a new and progressive policy, and particularly since its decision to publish an up-to-date journal devoted to matters of military medicine, surgery and hygiene, the membership of the association has increased by more than one hundred, and applications for membership are being received at the rate of about twenty-five a month. The association is now on a sound basis as regards finances and membership, and enters on its future broader field of work in the improvement of conditions in the military and naval establishments of the National and State forces with the brightest prospects of success.

Study of Hygiene Recommended for West Point Cadets.—The Board of Visitors at the United States Military Academy, West Point, has recently expressed itself in its official report to the Secretary of War, with respect to the addition of the subject of military hygiene to the prescribed course of study in the following language:

"The board feels that the time has come when those in charge of the academy should realize that there are other requisites to a well-rounded education as applied to the soldier, than those that relate to mathematics and their application. There has been too great a tendency to cling to old educational traditions that have influenced, if not entirely shaped, the curriculum from the foundation of the academy. . . . while in the academy he should have time and opportunity for the study of . . . military hygiene."

Philadelphia County Medical Society.—At a stated meeting held November 27, Dr. Robert N. Willson, Jr., read a paper entitled "Tetanus Appearing in the Course of Vaccinia: Report of a Case." He presented evidence tending to show that in cases of tetanus complicating vaccination the condition was one of secondary infection due to carelessness in the management of the wound and not related directly to the act of vaccination itself or to contamination of the virus. Dr. F. Savary Pearce read a paper entitled "Trophoneurosis Affecting the Hair: Photographs of a Case." The patient was a young woman of neurotic temperament in whom in the sequence of some emotional disturbance there occurred first alopecia, followed by partial whitening of the hair. Dr. Alfred Gordon read a paper entitled "The Effect of Nitroglycerin in Vascular Disturbances of some Functions of the Brain, with Reports of two Cases."

Philadelphia Neurological Society.—At a stated meeting, held November 26, Dr. F. X. Dercum exhibited "A Case of Hemilesion of the Cord with Brown-Séquard Syndrome." The patient was a man suffering from syphilis, who presented paralysis of one lower extremity, with loss of painful and thermal sensibility and preservation of tactile sensibility in the opposite extremity.

Dr. John K. Mitchell presented "A Case Exhibiting the Results of Co-ordination Exercises." As a result of treatment the patient regained considerable skill in walking. Dr. D. J. McCarthy presented "A Case of Postapoplectic Hypertonia." The patient was a woman in whom, without marked loss of motor-power upon one side, transitory tonic spasm occurred in certain of the muscles. Dr. Wm. G. Spiller exhibited [illegible] presenting loss of [illegible] movement with coarse tremor [illegible] side of [illegible] symptoms of optic neuritis and exaggerated knee-jerks. Dr. C. L. Allen exhibited "An Unusual Tumor of the Brain," which macroscopically and microscopically presented the appearances of a cholesteatoma. Dr. Chas. W. Burr exhibited "A Case of Aphasia" occurring in a young man who had been a painter and had indulged in alcohol excessively. As a result of educational exercises the man learned to speak. He used single words by preference, and principally nouns, and his language was dissociated. He could see and hear, and he learned to recognize letters and a few words under certain conditions. There was no motor disability. Dr. Wm. G. Spiller read a paper entitled "Remarks on the Tract Described by Me—the Direct Ventrolateral Pyramidal Tract." This is a tract that was discovered in the brain from a case of hemiplegia, and it had been traced from the medulla to the cervical cord. It has since been observed by other investigators. Dr. Spiller maintains that it is distinct from the tract of Helweg, but concerning its significance he had no information to give.

Jewish Hospital, Philadelphia.—Mr. Meyer Guggenheim of New York has proffered the Jewish Hospital of Philadelphia a gift of $60,000 for the erection of a building for the treatment of private patients, to be known as the "Meyer Guggenheim Private Hospital," and the income from which shall be devoted to the charitable work of the institute.

The Report of the Health Officer of the District of Columbia, for the year ending June 30th last, shows a considerable increase in the amount of work performed in the chemical laboratory of the Health Department over that of the previous year. In all 1,226 samples of food were examined, of which number 550 samples were milk. Of the samples of milk 15.1 per cent. of those secured from local city dealers were below standard, while of the county samples taken at the Baltimore and Potomac depot only 4 per cent. were below standard. Of the samples of cream shipped into the city somewhat more than one-half were found to be below the legal standard. Samples of water were analyzed in 54 cases from private wells and of these 37 wells were condemned as a result of the chemical analyses. Samples of water examined from dairy farms and dairies numbered 33, and of this number 14 were condemned. Samples taken from twelve public wells resulted in the closing of three of these wells. With respect to foods, a number of samples sold as lard were found to be mixtures of beef fat and cottonseed oil. Eight samples of vinegar were found to be imitations made from beech shavings, and a number of samples of cider were found to be preserved with salicylic acid. Samples of olive oil were frequently found to be cottonseed oil, and the butter of the cheaper groceries was often found to be oleomargarin. With respect to medicines, phenacetin was found to be frequently adulterated with acetanilid; while of a large number of samples of chlorinated lime examined, in not a single instance was the amount of chlorine present equal to that prescribed by the U. S. Pharmacopœia. The amount of available chlorine gas in the samples secured varied from 5 to 17.5 per cent. The increased work done in the chemical laboratory of the Board of Health has largely been due to an increase in the number of food inspectors recently authorized by Congress.

Naval Cruiser Condemned by Surgeons.—In the opinion of Naval Surgeons, the U. S. Cruiser Atlanta, now at Genoa, Italy, is unfit for human habitation. Surgeon Harris recently on duty on

this ship, in a report to the Surgeon-General of the Navy with regard to its condition, says that from a sanitary point of view the *Albany* is so radically wrong as regards construction that it is almost impossible to relate in detail the necessary changes which will have to be made before this ship will become a reasonably sanitary vessel. "It is impossible to overestimate the danger to the health of those who are berthed in the wing passages," says the report, "should the weather require the ship to be battened down for several days. With the temperature of 136 degrees Fahrenheit it is obvious that people could not live in these places."

The *Albany* is a ship which was designed and partly constructed by English builders for the Brazilian Government, and which was acquired in an unfinished condition by the United States from the latter, as an emergency purchase, just before the declaration of war with Spain.

Commended for Bravery.—Private William R. Jones of the Hospital Corps of the Army was recently officially commended from the office of the Surgeon-General for energy and bravery exhibited by him in stopping the runaway team attached to an army ambulance conveying six insane soldiers to the Government Hospital for the Insane in Washington. Private Jones, by great strength and dexterity, succeeded in catching one of the horses by the bit and throwing both of the struggling animals to the ground, just as they were about to carry the occupants of the ambulance to almost certain death down the steep hill on the Capitol grounds.

Lance Acting Hospital Stewards.—A paragraph has been added to army regulations which authorizes the appointment of lance acting hospital stewards, in order that privates of this Hospital Corps may be better tested as to their fitness for promotion to the grade of non-commissioned officer. These appointments carry with them no extra pay and allowances, but the appointees are entitled to receive obedience and respect from privates in the performance of their duties. The surgeon-general and chief surgeon make these appointments, which remain in force for three months, but may be renewed for an additional period of three months. The lance acting hospital steward will wear the uniform of a private of the Hospital Corps, with the addition of a chevron having a single bar of braid.

Recent Deaths of Army Medical Officers in the Philippines include, during the past few weeks, the names of Dr. R. S. Griswold, major and surgeon, who was killed in action; Dr. J. C. Orr, captain and assistant surgeon, who died of dysentery; and G. S. Dean, contract surgeon, who succumbed to tuberculosis. The same reports brought news of the death of a hospital steward, from exhaustion, and of a private of the hospital corps, who died from sunstroke. An officer of the line who recently returned from the Philippines for treatment states that at the time he was a patient in a Manila hospital, six of the nine other occupants of his ward were medical officers, and of these six, four were suffering from wounds received in action. Facts of this sort furnish the best of evidence of the active work being done by the Medical Department of the Army in the field, and show that those attached to this department, though nominally non-combatants and under protection of neutrality, suffer at least their full proportion of wounds and casualties. If the history of the Medical Department of the Army and of the Hospital Corps for the period including the war with Spain, the Philippine insurrection, and the China expedition is ever written, it will be replete with instances of heroism, fortitude under difficulties, and self-sacrifice, which would have brought honors and preferment in any other branch of the military service.

The Cholera is still epidemic in Batavia, nearly six thousand deaths from this disease having been reported there during October and the first half of November.

Obituary Notes. Dr. [illegible] S. Berry died at his home in Paterson, N. J., on November 28, at the age of fifty-eight years. He was born in England and came to this country in 1867. Soon afterward he began the study of medicine and was graduated from Bellevue Hospital Medical College in this city in 1875. He settled in Paterson and rapidly built up a large practice.

Mrs. McNeal, a woman physician, and wife of a physician of Ann Arbor, Mich., was lost at sea by being washed overboard from the American Line steamer *Belgenland*, on November 24, as the vessel was passing the Nantucket lightship.

Dr. Henry C. Houghton, a prominent homœopathic physician of this city, died suddenly on December 1. He was a graduate of the New York University Medical College in 1867. At the time of his death he was Professor of Physiology in the New York Homœopathic Medical College and of the New York Medical College and Hospital for Women. He was Dean and Professor of Otology at the New York Ophthalmic Hospital. He was President of the New York State and New York County Homœopathic Medical Societies.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SMALLPOX — BIRTHDAY HONORS — HOSPITAL LEGACY — PRINCE'S FUND — EPITHELIAL CANCER — PROGNOSIS OF NERVOUS DISEASES — RESTAURANT KITCHENS.

London, November 15, 1901.

Smallpox is not abating. From twelve to fourteen new cases a day have been reported during the week. Yesterday there were sixteen. Comparison with the spread of the disease in the 1893-94 epidemic shows that the present is taking the same course—pressing in the most crowded parts.

Of course, overcrowding must facilitate distribution. In 1893-94 shelters for the homeless played an important part in spreading it.

The County Council has issued a return of all cases this year. Up to the 14th instant they numbered 673. Of these 574 were reported in the eleven weeks ending November 2.

Much grumbling at the Asylums Board has been heard. They were warned by the medical superintendents of the hospitals in January, 1900, to prepare for an outbreak, but did nothing until it was upon them; so now they have to push on the erection of temporary buildings at all cost.

There is too much divided authority for effective sanitary control. We commit the lodging houses to the County Council; vaccination to the boards of guardians; the removal of cases to borough councils, and the care of them, when they reach the hospitals, to the asylums board. But no one seems to be authorized to sequestrate contacts, and there are other points on which some legislation seems necessary.

Pity the poor anti-vacs. They had the annual meeting of the league on Wednesday, when thirty delegates assembled to hear the president, a lieutenant-colonel, declare that the recrudescence of smallpox is due to a resumption of vaccination!

The "birthday honors" list is a brief one, and disappointing to many who thought it might prove a long one, as the first of the new reign. A knighthood is conferred on Mr. G. A. Critchett, the King's Ophthalmic Surgeon. The C.M.G. on Dr. Henderson, P.M.O. of the Gold Coast; Lieutenant-Colonel Gimlette, M.D., and Major T. H. Hill of the Indian service, in which also four officers received the Kaisar-i-Hind medal.

Twelve London hospitals are to divide between them

the residue of an estate estimated at about £120,000 bequeathed by Mr. Whiting.

It is proposed to offer to the King as a coronation gift a large sum to be collected for the purposes of the Prince of Wales's hospital fund which he founded.

At the Clinical Society on Friday, Mr. Moynihan read a paper on the "Operative Treatment of Cancer of the Pyloric Portion of the Stomach." Remarking on the great frequency of recurrence (estimated by Hemmater at 69 per cent. of operations), he said, to prevent this the operation must be based on a knowledge of the mode of invasion of the primary growth and of the lymphatic distribution and position of the glands into which the vessels drain. Having considered these points, he went on to describe three chief lymphatic areas; viz., an area along the lesser curvature; another, along the greater curvature; a third, comprising a greater tuberosity, extending up to the œsophagus, and on the greater curvature as far as the limit of supply of the left gastro-epiploic artery, as far as the gastrosplenic omentum. Mr. Moynihan finds that cancer mostly commences near the pylorus and spreads in the two former areas, the "isolated area" being very rarely affected. Accordingly, to insure complete removal of the primary growth, with the lymphatics and glands involved, he said it is necessary to remove the stomach as far up on the lesser curvature as the point of abutment of the coronary artery, and on the greater curvature as far as the gastrosplenic omentum; also, to remove the first portion of the duodenum. He described the operation he proposes to accomplish this.

Some discussion followed, in which the views propounded in the paper did not receive much support, though great dissatisfaction was expressed with the existing methods, and the physicians were pressed by the surgeons for earlier diagnosis, one gentleman suggesting that, instead of waiting for a definite tumor, they should get an exploratory incision made. It was said, too, that extension to the duodenum was very rare—not having been met with in the course of nine years' post-mortem work at St. Bartholomew's hospital, in which Dr. Moore said that in eleven cases out of thirty the whole wall of the stomach was involved, so that no area could be regarded as exempt. In fourteen of the thirty cases there were growths in the liver, often small and not perceptible during life; in some, secondary growths were on the under side of the diaphragm, and in about a third the lumbar glands were enlarged.

It was said, further, that the feeling of late had rather grown against the removal of pyloric growths, and a preference was expressed for short-circuiting.

In reply, Mr. Moynihan said that the growth was in a part which admitted removal in 70 per cent. of cases. As to diagnosis, a patient with gastric trouble at an age when cancer might be expected and with an absence of hydrochloric acid—a most important point—whatever the physical and clinical signs, should have the opportunity of an exploratory incision. Even at this early stage radical operation might not be permissible on account of the extent of the growth. As to gastroenterostomy, life after it was not to be compared with that after the more radical measure. Statistics show a great clear gain after the latter. The improvement after gastroenterostomy was great and immediate, but ephemeral.

The Bradshaw Lecture (I told you the origin of this endowment in my last letter) was delivered this year at the Royal College of Physicians by Dr. Judson Bury of Manchester, who took for his subject "Prognosis in Relation to Disease of the Nervous System." He began by remarking that when we enter into practice we are apt to separate diseases, from a prognostic point of view, into curable and incurable; but, with increasing experience of the course of morbid processes, we find ourselves less able to draw sharp distinctions between their ultimate results. We find that accurate prognosis is about impossible, and even an approximate forecast presents great difficulties which are perhaps more prominent in nervous diseases than those affecting other tissues. It is usually easier to make a regional than a pathological diagnosis, and this will continue to be the case until our knowledge of the causes of the disease has attained a firmer basis. Our ignorance of etiology and of general pathology in its broadest meaning makes our diagnosis and prognosis too often imperfect and erroneous. Dr. Bury passed in review our knowledge of some of the essential factors in the framing of a prognosis: as the attacking agent, the lesion—its size, situation, and nature—the results. The influences at work are manifold, and the effects are exceedingly complicated. How then are we to interpret the results?

The only manifestations to us are symptoms, and these depend, not on all, but only on some of the results. Moreover, they vary in different persons quite apart from the severity, distribution, and nature of the lesion. Examples of this were given by the lecturer, who related some carefully observed cases illustrating the want of correlation between symptoms and morbid anatomy. One of these was remarkable in that definite objective signs of brain disease observed both in Manchester and London passed completely away, and the patient, a female, aged twenty-two, regained health and resumed her occupation. Others went to show that the downward progress of the majority of cases of serious nerve disease is by no means through a constant succession of regular steps, but presents a most irregular course with infinite variations in kind and in time of succession. An arrest of a chronic disease may occur at any stage; and while, as a rule, it is only temporary, it may be permanent. Sometimes, however, improvement so prolonged as to seem like recovery may be followed by symptoms almost malignant in their severity and rapidity of progress.

How explain these variations?

Finding it so difficult to understand the ups and downs on the hypothesis of primary progressive degeneration of neurons, owing to exhaustion of their specific vital energy and apart from the direct action of toxins circulating in the blood, Dr. Bury suggested that the most common existing cause of these diseases is a poison. The fluctuations mentioned reminded him, in a way, of the temperature chart of a prolonged case of typhoid fever in which, at irregular intervals, a series of high temperatures alternated with a series of low ones, the high curve corresponding with a fresh development of toxins, the low curve to abatement of their action.

In relation to treatment, the toxin view is certainly the more encouraging, as it gives us the indications to eliminate the poison and neutralize its effects. But, unfortunately, Dr. Bury could give us no information as to the nature of the poison, nor of the way in which it enters the circulation. Till we know these points, as we do, for instance, in the case of lead poisoning, our treatment will be empirical and often futile, though the want of this knowledge is but a stimulus to further investigations—clinical, pathological, and chemical.

Some nauseating revelations are being made about the state of hotel and restaurant kitchens. Dark underground places, even cellars, are in some cases fitted up for cooking in. They often adjoin lavatories and urinals. The whole, we are told, sometimes being a single apartment.

Nothing so bad has been exposed since Dr. Waldo revealed the condition of underground bakehouses, and thereby enforced reform.

Dr. Waldo is one of our most trusted sanitarians. He was M.O.H. in Southwark when he led the agitation on bakeries. He is now M.O.H. to the Temple and Coroner to the city. You will remember his Milroy Lectures of which I gave you some account, and in which he pointed out how much horse dung enters into the dust of cities and is a danger.

He favors the licensing of restaurant kitchens, and placing them under the control of the County Council.

New ones would then have to satisfy the architect as to the provision for cooking in sanitary surroundings, and the old ones would have to undergo extensive alterations. All would be inspected annually and at other intervals.

You may imagine what is likely to be the condition of cooking apartments in such places as I have mentioned, under no sanitary control, and peopled by German and French servants. To read some of the newspaper accounts is a sure destroyer of appetite.

COSMETIC SURGERY.

TO THE EDITOR OF THE MEDICAL RECORD:

VIENNA, November 17, 1901.

SIR: I take the liberty to write to you concerning a procedure in cosmetic surgery which has been practised here now for some months, and is followed by such astonishingly good results that I thought it might be of more than passing interest to the readers of your journal.

The practice consists in the subcutaneous injection of a preparation of paraffin over bony excavations which have resulted either after operation or from disease or from congenital causes.

The injection of paraffin has been accomplished now frequently for saddle-nose, with most remarkable results, and, as I have seen, with absolute correction of the deformity. The needle is inserted over the glabella and is then passed down to the lowest point of the excavation, and as the preparation is being slowly injected the needle is slowly withdrawn, care being exerted that the injection infiltrates only the subcutaneous connective tissue. With the fingers of the left hand and while still warm, the paraffin is molded. Practically no irritation occurs either as an immediate or subsequent result, those cases

which have been shown [illegible] for over a year show a perfect tolerance on the part of the tissues and a permanent correction of the deformity.

This same procedure has been accomplished in order to elevate a depressed scar after operation for disease of the mastoid, but with less success, but I believe is adaptable to many other deformities which hitherto have remained uncorrected. The preparation is made by mixing together the solid and the soft paraffin of commerce until a mixture is obtained which has a melting point of 41° C. The paraffin is then sterilized and with gentle warming becomes sufficiently fluid to use in a syringe. Needless to say, it is well to warm the syringe also, and for this purpose hot water answers every requisite.

Hoping that this will prove of interest to you, I am

Yours truly,
EUGENE H. EISING, A.M., M.D.

IX. Hoffmann-La Roche.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Nov. 28, 1901.

Abscess in the Posterior Mediastinum in Connection with Pott's Disease.—Joel E. Goldthwaite reports a case in which operation was performed on an apparently dying child, an opening being made directly into the abscess, and drainage by means of a gauze wick established. The child rallied and made a good recovery. The author wishes to emphasize the importance and possibility of operation for the drainage of abscess in the posterior mediastinum when its presence causes such serious pressure symptoms as paroxysmal dyspnœa, with more or less tubular or metallic breathing. In case the abscess does not present under the incision, puncture of the spine at the seat of the disease is probably the safest procedure, even though it drains the abscess through the neck of the sac, theoretically the least favorable position.

A Case of Papillary Adenocystoma of the Thyroid Gland.—Harry C. Low reports the case of a woman of forty-nine years, suffering from a tumor situated in the median line of the neck, measuring about eighteen inches in circumference. It extended down behind the sternum, out under the sternomastoid muscles, and up to the lower jaw. It moved a respiration, and was not adherent to the skin. There was no sign of exophthalmic goiter. The tumor was removed under local anæsthesia with 1 to 1000 solution of cocaine. It was found to be a simple papillary adenocystoma. There was no evidence of any solid growth, nor any suggestion of malignancy. A tumor of this type is not very common in the thyroid. Its position among tumors remains to be settled. At least it is clinically a tumor to be removed for the sake of convenience, if not of its dangers, as a malignant growth. Future studies of these tumors may show their significance.

Pathological Lesions in Rheumatoid Arthritis.—C. F. Painter holds that the bacterial etiology of this disease, at least in the form that Bannatyne claims (the development locally in the joint of bacteria which manufacture toxins that, locally acting, injure the membrane and bones, producing the characteristic lesions), is not proved. This point is established by these facts: (1) Failure to demonstrate satisfactorily the organism itself, and the equally significant fact that the lesions found in the joint tissues are not such as are produced by any bacterial cause. (2) That the "chronic" stage in the disease does not present lesions, either gross or histological, which are at all derivative from the "acute" stage, and that therefore we must exclude from rheumatoid classifications any disease with hypertrophic bone lesions. (3) It is suggested, though not proved, that the changes in rheumatoid arthritis may be due to faulty metabolism, the absorption from the digestive tract of toxins, or some chemical product of intestinal digestion, which ought not to be thus absorbed, if all tissues were properly performing their functions.

Journal of the American Medical Association, Nov. 30, 1901.

Dissecting Abscess of the Abdominal Wall Producing Deformity Simulating Pott's Disease.—J. B. Bullitt reports a case and submits the following conclusions: (1) Abscesses of the abdominal wall without any connection with the abdominal cavity occur most frequently as a result of typhoid fever and readily heal after incision and drainage. (2) The larger dissecting abscesses of the abdominal wall communicate at their inception with some portion of the intestinal tract, occur most frequently as a sequela of typhoid fever or appendicitis, and result from an adhesion between the parietal peritoneum and a viscus, with perforation of the latter. After rupture, such abscesses follow the course of fecal fistula, healing sometimes spontaneously or as a result of incision with drainage only after the communication with the intestine has become obliterated. This obliteration sometimes occurs spontaneously, sometimes must be brought about by operative procedure. (3) A dissecting abscess may produce symptoms and deformity simulating Pott's disease; on the other hand, Pott's disease with abscess appearing after an attack of typhoid fever may be confounded with abscess resulting from the typhoidal process.

The Indications for Operation in Calculous Nephritis and Ureteritis.—C. L. Leonard says that the differentiation between the cases demanding immediate operation and those demanding a conservative, expectant treatment is based upon the result of x-ray examination. The symptoms suggesting the propriety of expectant treatment in cases in which small calculi have been located in the ureters are: A fairly constant dull ache in the lumbar region or along the line of the ureters, with recent and repeated attacks of more acute pain, with or without microscopic evidences in the urine of the presence and recent progression of a calculus. If the Röntgen picture also shows the shadow of an enlarged hydro- or pyonephrotic kidney, and tenderness can be elicited over the kidney and along the line of the ureter, they make more probable the subsequent passage of the calculus. These symptoms, in conjunction with the localization of a small calculus or calculi in the male ureters by the Röntgen method, are sufficient indications for adopting a conservative, expectant course of treatment. They sanction a delay, since they furnish absolute knowledge regarding the position of the calculus, so that any urgent symptom can be met by immediate operation upon a lesion that has already been determined. During such expectant treatment the condition of the kidney must be carefully watched by frequent urinalysis and quantitative estimations of the amount of urea. The employment of all exploratory instruments in the male, where there is no infection, is to be avoided. The segregator, the cystoscope, the vesicle sound and the ureteral catheter are all valuable instruments in diagnosis, but their employment in aseptic cases is a question that is still *sub judice*.

Acute Cholecystitis and Cholangitis as a Complication of Gallstones.—D. W. Eisenrath reports a case operated on unsuccessfully. From a study of the problems it suggests, he calls attention to the following points: (1) From observations on man and animals during life and an autopsy we can conclude that in the majority of cases the bile is sterile under normal conditions. This holds for the entire system of passages with the exception of the cystic or duct close to the duodenum, where many investigators have found microorganisms even when there was no obstruction to the flow of bile. (2) Bile is a pure culture medium for germ growth. It probably contains a substance which inhibits the growth of the majority of colon and typhoid bacilli. (3) Infection of the bile passages may be either descending (hæmatogenous) or ascending from the duodenum along the common duct. The latter is the far more common mode. Any interference with the contractility of the gall-bladder musculature or the presence of foreign bodies in the gall-bladder causes a marked increase in the number of microorganisms in the bile passages. (4) As to the relation between infection and gallstones, it may be said that of prime importance in the formation of the latter is infection, usually with the colon or typhoid bacillus. These infective agents set up a catarrh of the gall-bladder and the bile ducts, and when the nuclei of the stones, which most frequently consist of masses of epithelium and fat drops, are allowed to remain in the gall-bladder, through some cause which favors bile stagnation, gallstones are formed. When colon or typhoid bacilli are injected into the gall-bladder in small numbers, they soon find their way along the bile ducts into the liver, and cause extensive changes in the parenchyma and in the gall-bladder, namely, evidences of severe cholecystitis, necrosis of liver cells in the central portions of each lobule, and interstitial changes along the interlobular vessels.

Effect of Direct, Alternating Tesla Currents and *X*-Rays on Bacteria.—F. R. Zeit presents the following conclusions: 1. A continuous current of 265 to 320 milliampères passed through bouillon cultures kills bacteria of low thermal death points in ten minutes by the production of heat. 2. A continuous current of 48 milliampères passed through bouillon cultures for from two to three hours does not kill even non-resistant forms of bacteria. 3. A continuous current of 100 milliampères passed through bouillon cultures for seventy-five minutes kills all non-resistant forms of bacteria even if the temperature is artificially kept below 37° C. The effect is due to the formation of germicidal electrolytic products in the culture. 4. A continuous current passed through bouillon cultures of bacteria produces a strongly acid reaction at

the positive pole in to the aeration [illegible] combines with oxygen to form hydrogen [illegible] strongly alkaline reaction of the [illegible] negative pole is due to the formation of [illegible] and the liberation of hydrogen in gas bubbles. With a current of 120 milliamperes for two hours [illegible] 8.552 milligrams of H_2SO_4 to neutralize [illegible] fluid at the negative pole, and all the most resistant forms of bacteria were destroyed at the positive pole, including anthrax and subtilis spores. 5. The current per se, current alone, by means of Du Bois-Reymond's method of non-polarizing electrodes and exclusion of chemical effects by ions in Krüger's sense, is neither bactericidal nor antiseptic. The apparent antiseptic effect on suspension of bacteria is due to electric osmose. 6. A magnetic field, either within a helix of wire or between the poles of a powerful electro-magnet, has no antiseptic or bactericidal effects whatever. 7. Alternating currents of a three-inch Ruhmkorff coil, passed through bouillon cultures for ten hours, favor growth and pigment production. 8. High frequency, high potential currents—Tesla currents—have neither antiseptic nor bactericidal properties when passed around a bacterial suspension within a solenoid. When exposed to the brush discharges, ozone is produced and kills the bacteria. 9. Bouillon and hydrocele-fluid cultures in test-tubes of non-resistant forms of bacteria could not be killed by Röntgen rays after forty-eight hours' exposure at a distance of 20 mm. from the tube. 10. Suspensions of bacteria in agar plates and exposed for four hours to the rays, according to Rieder's plan, were not killed. 11. Tuberculous sputum exposed to the Röntgen rays for six hours at a distance of 20 mm. from the tube, caused acute miliary tuberculosis of all the guinea-pigs inoculated with it. 12. Röntgen rays have no direct bactericidal properties. The clinical results must be explained by other factors, possibly the production of ozone, hypochlorous acid, extensive necrosis of the deeper layers of the skin, and phagocytosis.

New York Medical Journal, November 30, 1901.

The Blood in Infancy and Childhood.—Gertrude U. Light notes that the three specific and characteristic factors of the changes in the blood of early life are as follows: (1) The blood of an infant tends constantly to resume embryonal characteristics when the clinical balance is disturbed. (2) Such disturbances produce blood changes out of proportion to the exciting cause, as measured by the standard of later life. 3. Lymphocytosis is pronounced. Clinically, increase of the spleen in the various anæmias of infancy in rickets, syphilis, and chronic intestinal affections, etc., tends to enlargement, that the single factor, splenomegaly, has not the significance of later life, and the diagnosis must be made on the intrinsic findings in the blood and viscera.

Cholecystectomy for Gallstones.—C. L. Gibson submits the following conclusions. In [illegible] cases it is an extremely simple and safe operation. It is a curative operation, doing away with subsequent attacks of cholecystitis, and, more completely, of renewed stone formation. It eliminates the disagreeable possibilities of long-continued biliary and mucous fistulæ. It is indicated in certain technical conditions, such as atrophic or (for drainage) inaccessible bladder, obliteration of the cystic duct, or impacted stone in the cystic duct, and in hemorrhagic conditions of the gall-bladder. It is a prophylactic measure against the development of carcinoma on the site of long-standing irritation. It offers the prospect of a shorter and easier wound-healing and convalescence. It is not to be employed indiscriminately, but has its proper limitations and contraindications.

Frostbite of the Cornea Due to Excessive Application of Cold in the Treatment of Mild Mucopurulent Conjunctivitis in the New-born.—Two cases are reported by E. L. Meierhof. After the third day of the applications it was noted that the eyelids were closed, but not swollen, and were easily parted, exposing each eyeball freely; there was some thin mucopurulent secretion, but it was not very abundant. The inner surfaces of the lids were red, but not thickened; the bulbar portion of the conjunctiva was quite free from swelling or redness, but there was a slight clouding of the cornea. The suspension of cold was advised, and in place thereof was substituted a gentle heat applied at regular intervals by means of warm, moist cotton pads. In a few days the clouding disappeared. The writer assumes that the heat gave the necessary support for the proper restoration of nutrition, and aided in the absorption of the necrotic exudate from the superficial layer of the cornea.

Medical News, November 23, 1901.

"What Is the Use of Making a Diagnosis in Nervous Diseases, Since Nothing Can Be Done Anyway?"—Theodore Diller declares that, besides [illegible] or even [illegible] doubting upon the physician [illegible] prognosis, and giving [illegible] patient, his family, and [illegible] of the disease. [illegible] tested by his treatment [illegible] that of the acute infectious [illegible] can so comfort the patient and friends as the physician. The financial question, also, [illegible] in these cases. With the knowledge of what lies before them, the family can harbor their little fortune instead of wasting it on useless travel which will in no way benefit the invalid. Again, some nervous diseases are curable, and in all of them proper treatment is of the greatest importance. Finally, for the sake of his own mental training and his conscience, the physician should always endeavor to arrive at a correct diagnosis.

A Preliminary Note on the Sterilization of Catheters; a Bacteriological Study.—C. B. Nancrede and W. H. Hutchings conclude that: (1) An infected soft-rubber catheter cannot be completely sterilized by boiling under 4½ minutes. (2) Mechanical cleansing from all dried pus, coagulated blood, or mucus will render sterilization easier and more rapid. (3) Elastic (English web) catheters and soft-rubber catheters can be repeatedly boiled for five or more minutes without roughening of their surfaces or diminution of their elasticity and strength. (4) Chemical sterilization by immersion in a 1 to 2000 mercuric chloride solution for five minutes does not sterilize any variety of catheter which has become infected, at best only inhibiting the growth of the germs. (5) The results of experiments indicate that chemical sterilization should never be employed for catheters which are to be retained in the bladder for any length of time, unless subjected to a very prolonged action of the mercurial salt. (6) If corrosive sublimate is used, it must be in concentrated solution, and for a much longer time than the period usually considered sufficient. (7) Formalin vapor will sterilize infected instruments in twenty-four hours. (8) All methods of sterilization commonly employed should be continued for much longer periods than the minimum time required for destruction of germs in the laboratory. (9) English web catheters can apparently be more readily sterilized by heat than can soft-rubber catheters, probably on account of their interior construction.

Medical News, November 30, 1901.

Courvoisier's Law.—Richard C. Cabot states this law as follows: "When the common duct is obstructed by a stone dilatation of the gall-bladder is rare; when the common duct is obstructed by other causes, dilatation of the gall-bladder is common." The writer calls attention to the value of this law in the diagnosis of cases of chronic jaundice, with or without enlargement of the gall-bladder. He believes that this rule can be relied upon to an extent rarely possible in a matter so uncertain as physical diagnosis.

Report of a Case of Diaphragmatic Hernia.—H. D. Howe reports the case of a boy who, while he was "scorching" on his wheel, was hit by a cart, receiving the full force of the blow just below the left breast. He showed all the symptoms of shock, but no fracture was detected. Respiration was shallow on the wounded side, but the heart's action soon became regular and fairly strong. There was neither vomiting nor cough. At the end of six days the patient resumed his duties in a military school. It was over seven months from this time, when the patient was again admitted to the hospital. The trouble then began after violent exertion in a jumping match. The patient complained of nausea and a dull pain up and down the lower half of the sternum. There was a decrease in the respiratory movement of the lower half of the left chest, with distant breath sound. The heart was displaced to the right and upward. Its sounds were normal. The abdomen was somewhat scaphoid. The bowels were obstinately constipated. There was no abdominal tenderness. Vomiting was relieved by gastric lavage. The patient died ten days after admission to the hospital, having been nourished almost entirely by enemata. Emaciation had become extreme. He had been able to rest only in a sitting posture. Necropsy disclosed a rupture of the diaphragm 1½ by 1½ inches, near the center of the muscular portion, 1 inch to the left of the œsophageal opening. The stomach, transverse colon, upper part of the descending colon, and fully ½ of the great omentum were found in the left chest cavity. The heart was displaced to the right and upward. The patient's condition during his last sojourn in the hospital had been so critical that an operation could not be considered.

The Medical Record, November 30, 1901.

A Case of Pistol-Shot Wound of the Stomach, Liver, and Transverse Colon in a Pregnant Woman.—Andrew B. Gloninger reports the case of a young woman who was shot in the abdomen at close range. She was phlegmatic and showed little evidence of shock. The six entries made by the bullet were trimmed back and the edges brought together with Lembert sutures. The bullet was not found. The abdominal cavity was thoroughly flushed, a large drainage tube introduced, and the incision closed as usual. A high enema was given on the following day. Pain was controlled by morphine. Nutritive enemata were given, and the abdominal cavity was flushed out at frequent intervals (considerable partly digested food had escaped through the stomach wound into the abdominal cavity). On the third day, the patient had a little cracked ice and a little brandy, and on the fourth day two ounces of peptonized milk. On this day, there was a normal bowel movement. On the seventh day, the drainage tube was removed. Small doses of calomel were given, with occasional high enemata, to keep the bowels open. On the fourteenth day, the temperature, which on the twelfth day had risen to 102.4°, due to a stitch abscess, reached the normal point and recovery was uninterrupted. About four months later, the patient gave birth to a healthy female child. Four years later, the bullet was located by the use of the x-ray in the left innominate bone.

The Early Recognition and Management of Arterial Degeneration.—Louis Faugères Bishop states that arterial degeneration is the penalty of chronic intoxication, whether this be of overwork, of alcohol, of a too rich diet, or of syphilis. It is the smaller arteries that first give the signs of disordered function by offering an unhealthy resistance to the circulation of the blood and causing tension. It is this tension that leads to organic changes in the body. All the symptoms so familiar in advanced arteriosclerosis may be seen in a shadowy form in the earlier stages of the disease. Degeneration frequently first manifests itself as a tendency. Heredity is a powerful etiological factor. However, the life of the blood vessels depends chiefly upon the use that is made of them. There are two classes of individuals most given to this affection, viz., ruddy-complexioned persons of the gouty diathesis, and pallid persons of the nervous diathesis. The management of arterial degeneration consists more in hygienic measures than in the administration of drugs. Two drugs are distinctly contraindicated in the early stages, namely, iron and digitalis. The persistent use of alkalies, the abundant use of water, and the use of bitter tonics in small doses about complete the list of drugs useful in this affection. In neurasthenics, the bromides are of great value. The early recognition of arterial degeneration calls for the most careful judgment, and hasty conclusions from a single symptom must be avoided.

American Medicine, November 23, 1901.

A New Constituent of Bone.—William J. Gies states that this newly discovered substance, osseomucoid, is practically the same as the mucoid in tendon, cartilage, and other connective tissues. It not only responds to the general proteid tests, but appears to have the same solubilities and precipitative reaction as the other connective-tissue mucoids, and yields the same proportion of reducing substance on decomposition with mineral acids. Furthermore, the combustion equivalents of osseomucoid, chondromucoid, and tendomucoid are practically identical, indicating close chemical relationship of these glucoproteid products. It is probable, then, that ordinary compact bone contains mucin substance, and that in the process of ossification, the connective-tissue matrix is not completely removed. This fact makes it easier to understand the accumulation of mucoid in various pathological formations in osseous tissue.

Annular Pancreas.—Theo. Ticken reports a number of cases, and says in regard to the genesis of annular pancreas that, if the ventral and dorsal diverticula did not unite as they normally do, but each developed independently, there would be pancreatic tissue on either side of the intestine, and as growth proceeded, the bowel would soon be completely surrounded by granular tissue. In the semiannular type, the condition might be due to an overdevelopment of the head, which sends out processes, partly surrounding the bowel. If this hypertrophy should continue until the processes meet on opposite sides of the duodenum, there would be a true annular pancreas, and there is no reason why this could not occur. The accessory pancreas may be a factor in the production of diverticula of the intestine; or it may become the seat of tumor formation. It may obstruct the bowel, and cause great dilatation of the duodenum. In the event of tumor of the head of the pancreas, there would be early stenosis of the bowel, and probably occlusion of the bile ducts. This would be a puzzling condition and might simulate the appearance of "hour-glass" contraction of the stomach. The accumulation and decomposition of food in the duodenal sacculation is another possibility from which serious symptoms might arise.

American Medicine, November 30, 1901.

Some Thoughts on Rheumatism and Rheumatic Simulants.—James J. Walsh declares that three terms in medicine—rheumatism, gout, and catarrh—cover a multitude of diagnostic sins. The fact that serous membranes are prone to be the subject of rheumatic manifestations points to the conclusion that rheumatism is a mild, generalized infection. Besides the joint symptoms that occur in connection with microbic diseases of various kinds, there are a series of arthropathies which are due alone to the presence of toxins in the blood. Lead poisoning is an example. These toxæmic arthropathies are an important part of the rheumatic simulants. Arthritic neuroses form another class. Flat-foot symptoms, for example, are frequently taken for rheumatism. In explanation of the exaggeration of pain in damp weather, the author says that superficial nerves are more sensitive in damp weather, for the skin becomes cold and the circulation is so interfered with that the terminal nerve filaments do not receive their due supply of blood. Another class of rheumatic simulants consists of those suffering from some joint injury, causing a relaxation of the tissues around the injured joints. Old people often suffer from aching joints, from the tendency to connective-tissue formation. But the most important class of rheumatic simulants is found under the head of occupation neuroses. The most common type is that of brachialgia; this is seen in telegraphers, penmen, typewritists, motormen, etc. It is the rheumatic simulants that have given to rheumatism its bad name. True chronic rheumatism is much rarer than has been generally supposed.

Tuberculosis of the Sacroiliac Joint, Its Diagnosis and Treatment.—C. O. Thienhaus states that in the beginning of the disease, the patients complain of pain in the lumbar region or in the region of the hip-joint, chiefly when sitting down or getting up. When signs of general nervousness and unrest, perhaps with astasia tibiarum and other hysterical symptoms, are noted in patients between the ages of twenty and thirty-five, and do not yield readily to treatment, the possibility of tuberculosis of the iliosacral join tmust be considered, even when the hereditary history is negative. In many cases, there is a decided atrophy of the lower extremity of the affected side. Men, chiefly laborers, are prone to be afflicted with tuberculosis of the sacroiliac joint. A differential diagnosis must be made between this affection and several other kinds of abcesses, viz., that resulting from tuberculosis of the os sacrum alone, or of the inner plate of the os ilii, or the region of the acetabulum; the so-called phlegmonous processes of the iliac fossæ, tuberculosis or actinomycosis of the ileocæcum, tuberculosis of the ovary with abscess, dermoids, actinomycosis, and ecchinococcus of the pelvis, syphilis of the pelvis in the third state, and infected retroperitoneal glands; lastly, the so-called psoas abscess. In psoas abscess, the patient tries to rest the psoas muscle by flexion of the thigh and torsion to the other side. Treatment varies according to the state of the disease. In the beginning of a caries sicca, conservative treatment by rest in bed with extension or a plaster-of-Paris splint is indicated. Iodoform-glycerin injections, peroxide of hydrogen, and balsam of Peru, with good nourishment, are valuable. Operative treatment is very bloody and demands perfect technic and skill. The writer then briefly reports a case of Delbet's sacrocoxalgia fruste.

The Lancet, November 23, 1901.

The Etiology of Beriberi.—P. Manson discusses in full the dietetic and microbic theories giving in the main his adhesion to the latter. Though beriberi is a toxin-produced disease, we cannot say what the toxin is, what the germ producing it is, or where this germ resides. He adds that there are several points that investigators into the etiology of beriberi must be careful to attend to. (1) The diagnosis; they must avoid mistaking other forms of peripheral neuritis for that of beriberi. (2) They must bear in mind the possibility that the disease may not have been contracted at the place in which it is declared. (3) That the toxin which produces an outbreak of beriberi may have been imported as such and not manufactured, so to speak, locally. (4) They must carefully differentiate between predisposing or favoring conditions, such as overcrowding, heat, and moisture, bad food, etc., and the actual direct cause.

5 Finally, they must recognize that the actual cause must correspond in its geographical distribution with the geographical distribution of the disease.

Sulphur in the Treatment of Dysentery.—G. E. Richmond says that sulphur is from its solidity and non-absorbability an ideal intestinal antiseptic; that it passes along the whole intestinal tract is shown from the fact that it can be seen suspended as a yellow powder in watery motions. With sulphur, the stools become much less offensive and no trouble arises from flatulence. Whatever the true cause of dysentery, sulphur seems capable of controlling and curing it, and it is possible that it may be found of service in cases of summer diarrhœa and perhaps in cases of enteric fever. Several clinical histories are given. Acute cases were treated with sulphur and Dover's powder, and chronic cases with sulphur alone. The opium brings comfort to the patient, and by its inhibitory effect upon intestinal peristalsis controls the diarrhœa and keeps the ulcerated portion of the intestine at rest, and by this means allows the antiseptic qualities of the sulphur to take effect under the most favorable circumstances. The precise mode of action of sulphur in the intestines is more or less a matter of conjecture; it is, however, reasonable to believe that sulphuretted hydrogen and other sulphur acids are formed and inhibit the growth of the microorganism of dysentery.

A Note on Neisser's Test for Diphtheritic Bacilli.—L. Cobbett advises the use of Neisser's stain as likely to detect bacilli which may escape the usual methods of detection. In his experience this result has been obtained when the diphtheria bacilli were mixed with a crowd of Hofmann bacilli, the character of the culture not admitting of the satisfactory examination of single colonies. In these cases, Neisser's stain first revealed the diphtheria bacilli, and their subsequent isolation and examination of pure cultures showed that the stain had given the right indication. In such cases when the colonies of diphtheria bacilli are few in number and crowded with other sorts, it is often difficult and tedious to prepare a second cover-slip which shall contain the bacilli that one wishes to subject to Neisser's stain. Hence arises the necessity for applying the special stain to the original cover-slip. This may be floated off, after removing the cedar oil, with filter paper soaked in xylol, washed for a minute in 5-per-cent. acetic acid, and stained by the ordinary Neisser method. But frequently one desires to apply the test to a particular group of bacilli without moving the slide from the microscope. This led the author to try the device of applying a drop of 5-per-cent. acetic acid to one edge of the cover-slip and drawing the fluid under the glass by means of a small piece of filter paper placed on the other side. If the bacilli are watched while the acid is entering under the cover-slip, one sees first a current of fluid sweeping up loose bacilli and hurrying them away. A blue cloud next appears and blots out everything for a second and passes on. Then, once again the field is bright and clear, and the diphtheria bacilli, if such they are, show the characteristic polar bodies as if stained in the way Neisser recommended; only the bodies of the bacili are not brown, but pale-blue. Hofmann's bacilli also have a fairly characteristic appearance when treated in this way. They do not so easily decolorize as the diphtheria bacillus, and at about the middle of each half a good deal of blue usually remains. With diphtheria bacilli the change is instantaneous, and the picture revealed is often not inferior to that of a Neisser specimen stained in the usual way.

British Medical Journal, November 16, 1901.

On the Removal of Great Lengths of Intestine.—Alexander Blayney concludes that the question of exactly how much intestine may be removed without damage to nutrition concerns more the physiologist than the surgeon. The latter is confronted with a problem which admits of only one answer. His patient is in immediate danger of death, and the surgeon's first duty is to save his life. If he is dealing with gangrenous intestine, he must remove the whole of it, whether it measures a little more or less than 200 cm., he will not stop to inquire. The leaving behind of the smallest part of gangrenous gut means death, its complete removal may mean life. The teaching of clinical experience as indicated above would seem in cases uncomplicated by other lesions to point toward 200 cm. as being the limit about which the danger line fluctuates. Children can bear the removal of far more than adults.

A Case of Intussusception in an Aged Patient; Laparotomy; Recovery.—C. Clement Stead reports this case of a woman, aged seventy-two years. The patient had suffered from chronic constipation and had had several attacks of extreme flatulence during which there was colicky pain with great distention. On the present occasion, when she was at stool, she felt that something was going wrong, although she did not strain at all. On examination, a large mass was found protruding from the anus. Taxis failed to reduce it. Operation was begun six and one-quarter hours after the appearance of the intussusception. The greatest obstacle to reduction was at the sphincter ani, which was divided. The tumor was composed entirely of large intestine. Bit by bit of the bowel was gradually passed back into the abdomen. The peritoneal surface of the bowel was in very good condition, although congested. The wound was closed with a row of seven deep catgut sutures, through all the layers of the parietes, and a superficial continuous suture of horse hair. Convalescence was slow but uninterrupted, except for a small stitch abscess.

An Improved Incision in Laparotomy for the Prevention of Post-Operative Hernia.—Arthur H. Buck believes that division of aponeurosis without supporting muscle is bad, as is evidenced by the frequency of ventral hernia occurring after such a procedure, that division of muscle in the direction of the fibers cannot be satisfactory if it entails division of motor-nerve fibers; nor can such division be satisfactory unless supported by other uninjured muscle or aponeurosis. The writer advocates the following method: An incision is made through skin, superficial fascia, and fat, down to the anterior layers of the sheath of the rectus. The anterior layers of the sheath are divided with the point of the knife about an inch from the inner edge of the muscle, care being taken not to injure the muscle fibers. The inner part of the muscle is readily enucleated from its attachments to the sheath anteriorly, internally, and posteriorly. The abdomen is opened in the same vertical plane as the previous incisions. The transversalis fascia, subperitoneal fat, and peritoneum are divided, and (above the level of the fold of Douglas) the posterior layers of the muscle sheath. The posterior sheath, together with transversalis fascia, subperitoneal fat, and peritoneum are united by a continuous suture. Suture of the skin and fat is accomplished in the usual way. The writer believes that there is extreme improbability of hernia after this procedure.

British Medical Journal, November 23, 1901.

Syphilis Versus Tuberculosis.—Arthur Cooper describes the case of a man aged thirty-nine years who contracted syphilis. He had previously suffered from phthisis and had been obliged to winter abroad. Six years after he first contracted syphilis, he had an attack of partial left hemiplegia. Partial paraplegia developing into complete, finally came on. After the nervous system became affected by syphilis, the signs of phthisis steadily subsided. The patient gradually became stout and ruddy, cough and expectoration ceased, and he had an excellent appetite. Repeated examination of the chest revealed no sign of active disease. He finally died from an attack of acute nephritis which came on after a chill. [illegible]

Acute Rheumatism; Hyperpyrexia; Post-Febrile Mania; Recovery.—D. Hamilton Kyle describes the case of a man aged thirty-two years, who was attacked by acute rheumatism. The temperature during the course of the disease ran up at one time to 105°. Salicylates were given at first. He was delirious, and at one time semi-conscious, then he became actually maniacal. Sodium salicylate was stopped, and a mixture of potassium iodide and bromide with antipyrin was given. His mind again became clear, and the salicylate was begun again. A few days later he became convalescent. At last accounts, although otherwise well, the right knee joint was still swollen and painful on movement. The heart sounds were normal; the skin was desquamating very freely.

Atheromatous Ulceration of the Heart; Perforation; Sudden Death.—D. F. Anderson reports this case. The patient was a man of sixty-two years. He had not been feeling well for five days, suffering from pain in the chest, running through to the back, and being more intense on the left side. The heart sounds were distant, but no *bruits* were heard. The pulse was regular and strong. Linseed poultices were applied to the front and back of the chest. The next day after entering the hospital, he died. Necropsy showed the heart to be hypertrophied and dilated, and there was a perforation on the posterior wall of the left ventricle. It was in the center of an ecchymosed patch. The perforation corresponded with an ulcer. The branches of the coronary artery near the ulcer were blocked by atheromatous thrombi. These had evidently been the cause of the ulceration.

A Lecture on Chest Complications in Abdominal Disease; a Study in Diagnosis.—J. Mitchell Bruce describes various interesting cases illustrative of this

[illegible] He [illegible] ated d[illegible] the ab-domen and chest [illegible] the [illegible] actions [illegible] the stomach, [illegible] or other [illegible] viscera, or of the peritoneum itself, complicated [illegible] a secondary [illegible] of the chest [illegible] the first phenomenon noted is disease of the lungs, pleura, or pericardium, which proves to be secondary to an unrecognized lesion below the diaphragm. One of the cases reported is as follows: A medical student consulted the writer for distention and tenderness of the abdomen, accompanied by fever; chronic hepatitis was suspected, but soon there was heard friction over the base of the left lung, which was quickly followed by the development of crepitations upward. The case was clearly one of tuberculosis, involving first the peritoneum, then the left pleura and lung. Tuberculous peritonitis is not the only kind of peritonitis that may be associated with acute pleurisy and other complications within the chest. The commonest by far is perityphlitis, originating in appendicitis. In all diseases within the abdomen, particularly diseases of an inflammatory kind, the chest should be examined with special care. Physical examination of the base of the chest in obscure and serious abdominal cases should be repeated as often as examination of the abdomen itself. The reverse of these cases is perhaps less frequent, but quite as important. "Pleurisy" should never offer a satisfactory diagnosis. It is nothing more than an anatomical expression—inflammation of the pleura. A case described was that of a girl of eighteen, who was thought to be suffering from a simple serous pleurisy. The chief trouble proved to be a perigastric abscess. The writer warns his readers against going to the other extreme and imagining the discovery of association of diseases of the abdomen and chest which does not in reality exist.

Berliner klinische Wochenschrift, November 11, 1901.

Double Personality.—K Gumpertz describes the case of a ten-year-old girl who, after an early childhood of great seriousness and helpfulness in household matters, began to keep the eyes open while sleeping, and a little later began to change personalities with an aunt deceased eight years previously, and of whom she had very little actual knowledge. Normally, the child is quiet, self-possessed, and well behaved, but in the transposed state shows great restlessness and is abusive and violent. In the natural condition, she has no memory of what has occurred during the hypnoid time and is always fatigued and somnolent on awaking from it. No unusual knowledge or attributes are manifested while in the abnormal state, but simply all inhibition seems to be removed from the evil traits that are usually kept in check.

The Heredity of the Constitutional Factor of Tuberculosis.—F Martins believes that this subject deserves more attention than has of late been given to it, and thinks that only in this way will it be possible to explain why certain individuals, even though infected with tuberculosis, do not become diseased. The one method that is available in this study is one that heretofore has been unduly neglected, and that is scientific genealogy. Riffel has collected the family trees of a number of families inhabiting a small town, and from his results valuable conclusions are to be drawn. Schluter has taken these data, which unfortunately are not arranged in the manner necessary, and by rearranging them has produced some valuable results. Taking as examples two families, each descended from a couple living in the 18th century, tuberculosis keeps cropping up on all sides in the people whose ancestors were tuberculous, while numbers of other stock, even though they chanced to be thoroughly exposed, never developed the disease. The presence of a hereditary tuberculous taint is of high importance, while its absence affords a notable but still only relative immunity.

Deutsche medicinische Wochenschrift, November 14, 1901.

A Case of Poisoning by Oleander.—S Watett says that this plant is commonly kept in Bulgarian households for ornament, and also that decoctions of its leaves are frequently used by the women to produce abortion. Poisoning cases from this source are accordingly not rare, and he describes one occurring in a young girl. The symptoms, which developed immediately after drinking a considerable amount of a strong decoction of the leaves, consisted in great gastrointestinal irritation, with prolonged nausea and vomiting, headache, and slowing of the pulse, which did not return to normal for three weeks. In another instance, all the members of a family were poisoned by the perfume of the oleander flowers, prompt cessation of the disagreeable symptoms following the removal of the plants from the house.

Nerve Over-Excitation as a Cause of Autointoxication.—A V Poehl agrees with Verworn that fatigue is a manifestation of [illegible]. The latter believes that this is probably due to carbonic acid and perhaps to other soluble products of metabolism. The author is of the opinion that the lactic acid formed through excitation is the important factor, and that the diminished tissue respiration also plays a significant rôle and may be recognized by examination of the urine. By making analyses of the urine excreted after mental, sexual, and physical excesses, the following conclusions were reached: (1) Fatigue diminishes the alkalinity of the blood. (2) The activity of the oxidation processes is markedly decreased. (3) The amount of nitrogenous decomposition products in the tissue juices is increased. (4) The osmotic tension of the tissue juices and its coefficient are lowered. (5) The rate of flow through the uriniferous tubules is diminished. (6) The electrical conductivity of the tissue juices is lessened. The same therapy suffices for very different types of fatigue maladies, and the factors required are means to increase the lowered respiratory activity of the tissues.

Manganate Poisoning.—In an article entitled "The Metallic Nerve Poisons," H. Embden adds one to the list of metals capable of producing chronic intoxications through the slow absorption of small amounts. Four cases of poisoning have been observed by the author in manganate mills, and as all ran a similar course it seems probable that there is a manganism just as there is a plumbism. After œdema of the feet has been observed for some time, the nervous symptoms reach their full development in the course of the next few weeks. There is first weakness of the legs and back with a tendency to staggering and retropulsion, then the arms are more or less attacked, and, finally, disturbances of voice and speech appear. The patients seem perfectly well physically, yet are unable to do any heavy work on account of the palsies of various sets of muscles. There are no true atrophies or reactions of degeneration. The face acquires a mask-like expression, the reflexes are active, and there is a coarse tremor of the trunk, extremities, and head. No nystagmus or other eye-symptoms are to be discovered. The sexual function and sphincters remain untouched. In its general symptomatology the condition strongly resembles multiple sclerosis, but it is evidently a different disease. The therapy consists in removal from the conditions under which the manganate dust may be inhaled; the prognosis is good.

Uterine Inversion.—Gross believes that, in cases of simple uterine inversion, irreducible by ordinary means, it is advisable to perform laparotomy with combined efforts at reinversion, both vaginal and abdominal; dilatation of the cervix should be made and the parts replaced. In polypous uterine inversion, hysterectomy, either vaginal or abdominal, will often be the only method of treatment. This operation is always more or less grave, and is well followed by drainage of the pelvis.—*Gazette des Hôpitaux*, November 16, 1901.

Treatment of Inversion of the Uterus by Anterior Colpohysterotomy.—G. Gayet describes a case of this kind from which he concludes that irreducible uterine inversion should be treated (save in cases with special contraindication) by conservative operation with the knife. Among these operations the simplest is colpohysterotomy, followed by the replacement of the uterus. Posterior adhesions and retroversion are less to be feared from this operation, and the cervix is fixed by the attachment to the bladder. In the patient whose case is reported, there had never been any deviation of the organ, nor any tendency to prolapse.—*Lyon Médical*, November 17, 1901.

A Study of the Functional Troubles of the Pupil an Their Cause.—Bonsignorio reports some interesting experiments with various conditions of light and accommodation in a young and vigorous subject, the eye being in the state of accommodation and focused on a distant object. The subject was placed opposite a window at five o'clock in the afternoon in August, and he was looking at an object in the street. Examination with a magnifying glass showed the movements of contraction and dilation of the pupil to be from 9 to 12 per minute. The subject was next placed in a room lighted by the sunlight, and while he looked at the wall the movements of the pupil were determined to be from 9 to 12 per minute, not coincident with systole. Finally, the subject was put into a room artificially lighted, and, while looking at the wall, the movements of the pupil numbered about the same as before. Each one of these movements, like all movements of the iris, is composed of a series of small oscillations, two or three in number, and scarcely perceptible, the pupil only attaining its maximum diameter by successive oscillations.—*La Presse Médicale*, November 13, 1901.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 21, 1901.

HERMAN KNAPP, M.D., VICE-PRESIDENT, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Medicine.

The Diagnosis of Cirrhosis of the Liver.—Dr. JAMES C. WILSON of Philadelphia read a paper on this subject. He said that it was unfortunate that the name cirrhosis had come into use; for, while it had been applied originally because it signified a yellow or tawny color, and this was more or less descriptive of certain forms of this hepatic affection, it gave no direct and accurate conception of the pathological condition. It was now asserted that atrophic and hypertrophic cirrhoses of the liver are not, as formerly supposed, merely different varieties of the same disease, but totally different diseases. Again, the term atrophic cirrhosis was likewise misleading; for statistics had shown that the hob-nail liver, to which it had been originally applied, was not necessarily smaller than the normal, and might even be larger. No definition could be framed which would include, both pathologically and clinically, all forms of so-called cirrhosis of the liver. The one underlying pathological process common to all the varieties is an overgrowth of the connective tissue of the liver. Chronic interstitial hepatitis was a sufficiently comprehensive term, and should be more generally used. Certain infections, toxæmias, and mechanical irritation give rise to interstitial hepatitis. Not all forms of chronic interstitial hepatitis could be recognized. A high degree of atrophy may occur, provided the collateral circulation has been established without other symptoms directing attention to the liver. Adhesive pyelo-phlebitis closely resembles the atrophic form of interstitial hepatitis. The rapidity with which the peritoneal effusion re-forms after tapping is an important diagnostic sign. The hypertrophic form of interstitial hepatitis often presents insuperable difficulties of diagnosis in the early stage. The recurrence or persistence of jaundice, its intensity, and the presence of bile in the stools, were of diagnostic importance. After the disease had become established, the uniform enlargement of the liver, the splenic tumor, the occasional attacks of jaundice, and the fever were diagnostic. Chills and sweating are not common, thus serving to differentiate it from impacted gallstones. In terminal conditions, the diagnosis is a comparatively simple matter.

The Operative Treatment of Ascites in Cirrhosis of the Liver.—Dr. GEORGE EMERSON BREWER read this paper. He said that cirrhosis of the liver was admitted by all to be an incurable disease. It had been estimated that the average duration of life after the occurrence of ascites, in uncomplicated cirrhosis of the liver, is only eight weeks; the cases surviving repeated tappings show at autopsy other complicating conditions. While medical treatment could do much to relieve the early symptoms, the fatal termination could not be averted. The first operation done with the object of establishing a collateral circulation in cases of hepatic cirrhosis with ascites had been done in 1899, and had consisted in opening the abdominal cavity, evacuating the fluid, and stitching the omentum to the anterior abdominal wall. The patient died of shock. The more modern operation includes an additional feature, the vigorous rubbing of the upper surface of the liver and the under surface of the diaphragm with sterile gauze, so as to favor the formation of adhesions. That this collateral circulation is actually established had been demonstrated most conclusively post mortem. A number of cases had been reported in which this operation had been done, and the results afforded good ground for the belief that ascites can be cured in a fair proportion of cases without much risk. In the opinion of the reader of the paper, the operation is still in its experimental stage. At present, there was a high mortality, probably owing to the fact that the majority of physicians are not yet ready to recommend the operation until the disease process was already far advanced. According to statistics, at least five cases had been cured of ascites and had remained so for five years, while a number of others had apparently been cured, but a sufficient time had not yet elapsed to warrant them being reported as actual cures. A tabular statement was presented of the fifty-seven operative cases so far reported, with suggestions as to the clinical data needed in future reports, in order that a just estimate of the value of this comparatively new operation might be formed.

Report of a Successful Case.—Dr. F. TILDEN BROWN said that Osler and other medical authorities state that a not inconsiderable number of cases of atrophic cirrhosis of the liver improve after a variable number of tappings, and live for several years in comparative comfort. Unfortunately, however, the autopsy records of these cases are wanting. The speaker said that in his own case, about to be reported, it had seemed that the prolonged drainage had been an advantage, not only in removing the serious effusion, but in favoring the formation of a funnel-shaped mass of new tissue, of exceeding vascularity, around the drainage tube sinus. The splendid results attained by Morrison, in two out of his four cases, and the rational method which he had outlined, made it incumbent on others to adhere to that method pretty closely until we were in possession of a distinctly better technique. Dr. Brown then reported his case as follows: J. C., male, forty-three years of age, a laborer, had been three different times a patient in the Presbyterian Hospital. In July, 1888, on his first admission, there had been vomiting, along with dyspnœa and a slowly increasing abdominal girth. Abdominal paracentesis had relieved the symptoms, but there had been a gradual recurrence of the former symptoms, and he had again entered the hospital on March 27, 1880. The apex of the heart had not been palpable at that time, and the superficial veins of the abdomen were distended. The edge of the liver could not be felt. Paracentesis of the abdomen had been done on April 10, and the man had left the hospital improved shortly afterward. He had been readmitted on May 31 of the same year with an abdomen greatly distended, and with urine containing albumin and casts. Abdominal paracentesis was performed on June 1, and on seven other occasions between that date and August 20. In a period of a little over seven weeks a total quantity of 2,866 ounces of fluid was removed. On September 1, the circumference of the abdomen was forty-one inches. The next day he was operated upon under chloroform anæsthesia through a five-inch incision. The omentum was shriveled, and the veins were large and tense. The liver was hard and small, and showed the characteristic hob-nail surface. The peritoneal surfaces were vigorously rubbed with sponges, and one line of chromicized catgut sutures introduced. A drainage tube was employed. Vomiting was troublesome for the first few hours, and the bed was often wet with the serous overflow. During the second week the quantity of serous fluid was much less. The wound healed by primary union. On the twenty-third day the large glass tube was changed for a smaller one. On October 18 the abdomen had measured 32½ inches. On January 5, 1900, the superficial veins of the abdomen were found to be no longer prominent, and the percussion note over the abdomen was tympanitic. The liver dulness extended from the fifth rib to nearly the costal margin. The heart apex had descended since the previous April from the fourth to the fifth interspace, and liver dulness began at the fifth instead of at the fourth rib. It was now two years and two months since this operation had been done, and the patient had worked since then as a day laborer. The patient was presented for inspection. Dr. Brown's conclusions were: (1) The more rapid the accu-

mulations of ascitic fluid, the more the need for providing for prolonged drainage; (2) In advanced and apparently hopeless cases, there is the greatest necessity for thoroughly aseptic pelvic drainage, and (3) The advantage of Morrison's adhesive strapping had been conclusively shown during the after-treatment of his case.

Hypertrophic and Atrophic Cirrhosis in the Same Case.—Dr. MORRIS MANGES said that he had under his care a man whom he had advised to undergo this operation two years and a half ago. The man had only been tapped three times at that time, and he refused operation. He was now a bedridden invalid in a most pitiable condition, for he felt grateful if he could go three days without being tapped. The secondary changes induced in the stomach, heart, liver, and other organs add to the misery of such persons. A series of experiments had been made on dogs, which had demonstrated that the operation is not only feasible, but is capable of accomplishing a good deal in cases of pure cirrhosis of the liver. The few cases of cirrhosis which had been operated upon successfully more than outweigh the many unsuccessful ones. In 1897, the speaker said, Dr. A. P. Gerster had operated upon a case of cirrhosis, and at the operation it had been demonstrated to be of the hypertrophic form. About ten months later the case had come to autopsy, and the liver was then demonstrated to be the seat of an atrophic cirrhosis. This one positive case should do much to offset the claims of those who believe that hypertrophic cirrhosis and atrophic cirrhosis of the liver are two distinct diseases, and not merely different stages of the same disease.

The Diagnosis of Cirrhosis of the Liver.—Dr. GEORGE L. PEABODY said that in New York City it was well known that instances of distinctly atrophic cirrhosis of the liver are rare, while many cases of cirrhosis of the liver are met with in which the liver is of rather large size. He would, however, reserve the term hypertrophic cirrhosis for the cases of malignant jaundice. The latter are totally different from those of cirrhosis with large liver. Clinicians of large experience and the greatest skill had declared that it is impossible to diagnose cirrhosis of the liver in the early stage. He had been much interested in the case reported by Dr. Manges, in which a liver at first large and cirrhotic, had subsequently become a small cirrhotic liver. He had never seen such a case, and thought they must be extremely rare. He had had two cases of cirrhosis of the liver in which profuse hemorrhage from the stomach had been the first symptom that had directed attention to the underlying condition. In one of these cases, that of a young woman addicted to the excessive use of alcohol, death resulted from the first hemorrhage, yet at the autopsy the atrophic cirrhosis had not been specially marked. The interference with the return of the blood in the turgid œsophageal veins interferes with the circulation through the right azygos vein. It was this impaired venous return that explains the occurrence of right-sided hydrothorax. By palpation one could make out the size of the liver, and could tell something of its consistency, but more than this could rarely be done. The differential diagnosis from syphilis of the liver was important, particularly in view of the possibility of surgical intervention. In one case which he recalled, an exploratory operation had been done, and this had revealed syphilis of the liver. At that time the man had been in a very serious condition, but he had ultimately recovered under antisyphilitic treatment. The differential diagnosis from nutmeg liver could be made by the presence of the cardiac lesions. In cases of chronic peritonitis the fluid was apt to be bloody. It was well to remember that if we could not relieve many of these cases of cirrhosis of the liver with ascites, about one-fourth of them would succumb to tuberculosis. The surgeon should certainly be permitted to try to relieve by their skill these unfortunate persons.

Dr. ANDREW H. SMITH said that the old notion that a connective-tissue growth first takes place in the liver, and then shrinks, squeezing out of existence many of the hepatic cells, was not tenable in the light of modern pathology. One of the conditions likely to be confounded with cirrhosis of the liver was colloid cancer of the peritoneum. In one case of this kind that he had seen, several good diagnosticians had agreed on the diagnosis of cirrhosis of the liver, but tappings and the subsequent course of the case had demonstrated its true nature. He was surprised at Dr. Peabody's statement that tuberculosis is such a common complication of hepatic cirrhosis. There were a good many cases on record in which there had been no reaccumulation after a single tapping, and others in which the fluid had ceased to return after repeated tappings, even after as many as one hundred.

Another Successful Operative Case.—Dr. CHARLES H. PECK said that on June 11 he had operated upon a stoker on one of the French steamers. The urine contained no albumin or casts. There was great distention of the abdomen. He had been tapped twice at an interval of a few days, and then had been operated upon. The omentum was stitched to the parietal peritoneum with three tiers of chromicized catgut sutures. Very little shock had followed the operation, and the man had been relieved. He was tapped five times up to August 21, and then, after an interval of thirty-one days, had returned to France. A report, after a further interval of two weeks, stated that he was doing well and had had no return of the ascites.

Avoid Permanent Drainage.—Dr. BREWER closed the discussion. He said in view of the fact that in so many of the reported cases death had occurred from a peritonitis coming on so late, it seemed quite probable that septic infection had occurred in the course of the after-treatment. He was consequently disposed to think that continuous drainage was exceedingly dangerous and unnecessary, and that it would be better to operate quickly without permanent drainage.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 18, 1901.

PARKER SYMS, M.D., PRESIDENT.

Carcinoma of the Rectum in a Patient Seventy-eight Years of Age; Excision; Recovery.—Dr. JOHN F. ERDMANN presented this specimen. There was a history of emaciation and the passage of blood in each stool. There was no evidence of hemorrhoids or of stricture of the rectum, but there was some mucopurulent discharge in addition to the passage of blood at each stool and in the interim. Although the man was seventy-eight years of age, his physical condition was that of a man of fifty-five. Examination of the rectum showed a carcinomatous mass practically encircling the rectum within an inch of the anus, and extending upward for about three inches. There were no palpable glands in the pelvis. The patient was placed on the abdomen with the limbs in the Trendelenburg position. The entire diseased mass with the sphincter was readily extirpated. The patient had been up on the sixth day, and at the end of four weeks had been able to return to business. He had gained twenty pounds in the last few weeks.

Symposium on Typhoid Fever.—The subject was covered by the presentation of five communications, as follows:

Epidemiology of Typhoid Fever in New York.—Dr. JOHN H. HUDDLESTON read a paper on this subject, based on the reports of the inspectors of the health department for the past three years. He said that not a week passed without some cases being reported to the health department, and the number had varied from a minimum of seven in one week in March, 1900, to a maximum of 170 in September, 1901. The cases specially considered were 1,017, of which number 635 had been reported not to have been out of the Borough of Manhattan within the longest recognized period of incubation. There were 120 patients who had been

out of the city at a time which made it impossible to say whether or not the disease had been contracted in this city. There were 113 cases that had been clearly infected outside the city, though the first symptoms had developed after their arrival here. Ninety had come here with the disease. Apparently fifty-nine had contracted the disease from others in the family, and there were three instances in which the infection had occurred in laundries. Forty-four of the patients had been in the habit of bathing along the city water-front. The number of cases occurring in this city usually reached a maximum each year between September 15 and November 15. Studying the cases with reference to the milk supply, it had been found that 299 of the persons said that they had partaken of grocery milk, 206 had used dairy milk, and forty-two had used condensed milk, while thirty-six insisted that they had not used milk at all. Family infections had occurred not infrequently in the more unsanitary portions of the city, and it was worthy of note that in each instance the infection had begun with the spreading of the disease by a child.

The Blood in Typhoid Fever.—Dr. JAMES EWING discussed in this paper more particularly the question of immunity and the prospects of obtaining good results from serum treatment. He said that one would expect success to be achieved more easily in the serum treatment of typhoid fever than of diphtheria, yet all knew that experience had not borne out this theoretical view. Very recent reports had shown that the typhoid bacillus can be obtained from the blood in the majority of cases, even in an early stage of the disease, and also from the rose spots. In the great majority of cases, typhoid fever is a form of septicæmia or bacteriæmia, while diphtheria is a toxæmia. Again, there is a variation in the biological character of the bacilli and the character of the agglutinating substances liberated in the system. The bodies of typhoid bacilli contain poison which does not diffuse readily through fluids. The problem in the serum therapy of typhoid fever was the preparation of a serum which is principally bactericidal and not antitoxic as in the case of diphtheria. The author then discussed the question of immunity and showed the complexity of the problem of producing therapeutically efficient sera for combating typhoid fever.

Surgical Complications of Typhoid.—Dr. ROBERT ABBÉ discussed this topic. He said that the abscesses found in the skin and muscles often contain pure cultures of the typhoid bacillus. A not infrequent surgical complication is the ulceration of the laryngeal cartilages, usually in the later weeks of the disease. The cricoid cartilage and the arytenoids were the ones usually involved. This complication often demanded tracheotomy. Another common complication was femoral phlebitis, and it had often resulted in gangrene of the leg. The left femoral vein was attacked four times more often than the right, and this was apparently due to the situation of the vein on that side, which exposed it more than the right vein to pressure. Peritonitis was observed not infrequently in typhoid. That variety resulting from typhoid ulceration and perforation of the bowel was an especially interesting field to the surgeon. This perforation always takes place in the hyperæmic area of the ulcerated patch. He was of the opinion that impending ulceration of the bowel in typhoid fever was within the power of nature to heal, but it was a statement difficult of demonstration. If the physician could be informed that a perforation is imminent by some sign, such as tenderness on point pressure, it might be possible to avert it by the use of ice and opium. The perforation would always be found in the center of a gangrenous patch situated within fifteen or twenty inches of the caput coli, and the opening was usually large enough to admit a lead pencil. He thought that at the present time many exploratory laparotomies were made under cocaine anæsthesia, and this method should prove very useful when symptoms pointing to perforation and extravasation into the peritoneal cavity are present. He had operated upon four cases of typhoid perforation, with one recovery. Two of these patients were soldiers almost moribund at the time of operation.

Clinical Diagnosis of Typhoid Fever.—Dr. ALEXANDER LAMBERT made some extemporaneous remarks on this subject. He said that the difficulty in making the diagnosis was well shown by the fact that there are different bacteria giving rise to the same symptoms. In practice, his attention had often been called to the very low tension of the pulse in the very early days of typhoid fever; it was quite different from those observed in ordinary sepsis and in cases of malaria. In these early days also, one often met with a group of symptoms which would at least afford a hint as to the nature of the disease, *i. e.* the occurrence together of intense ringing in the ears, slight photophobia, and disordered taste. Unfortunately, the Widal reaction was not commonly observed until the tenth day, while the rose spots usually appear by the seventh day. Again, many cases would run through their entire course without the occurrence of the Widal reaction. At one time, it was thought that fully 98 per cent. of cases of typhoid fever would give this reaction, but sufficient consideration had not been given to the importance in this connection of the personal equation. It was a good plan, when taking blood for examination from a patient suspected of having typhoid, to make a smear of blood as well as put a drop on the slide. The blood could then be examined both for the Widal reaction and for the presence of malarial parasites, and also a differential count could be made. Normally, the mononuclear leucocytes were present in the proportion of 6 per cent., whereas in typhoid fever they frequently form 60 per cent. In conclusion, he wished to quote a remark made by Dr. Francis Delafield to his students in regard to the diagnosis of typhoid, "There is nothing too irregular for typhoid."

Some Remarks on the Treatment of Typhoid Fever.—Dr. A. ALEXANDER SMITH discussed this phase of the subject. He said that, while hopeful, he must confess to a considerable degree of skepticism regarding the specific and the abortive treatments of typhoid fever. He did not believe there was a single well-authenticated case on record of the successful abortive treatment of typhoid fever, though the disease sometimes aborts itself.

Baths.—Baths relieve the nervous manifestations, add to the patient's comfort, and probably act as a direct protection to the circulatory and respiratory systems. The form of bath which he preferred, both for hospital and private practice, was that known as the "bed bath." He had used it in his wards for a dozen years, and had found it just as efficacious as the tub bath.

The Bed Bath.—Two woolen blankets, rolled up, are placed at the edges of a rather narrow bed-cot, and over them a large piece of rubber sheeting or a large rubber horse-cover. A pillow is then placed at the head and another at the feet, thus making a trough in which the patient is placed. The bath should be begun at a temperature of 90° F., and the temperature gradually reduced, the rapidity of this reduction being graded according to the degree of discomfort produced. It was rarely necessary or desirable to give the bath at a temperature below 70°. If, after two or three days of treatment with the bath, it was found that the patient did not experience any great discomfort, he was at once put into a bath at a temperature of 75° or 70°. The duration of the bath was about ten minutes, and when concluded the pillow at the feet was removed and the water allowed to flow out into a receptacle. He had found such a bath more convenient and less terrifying to the patient and his relatives than the tub.

Precautions and Contraindications.—As he was of the opinion that a certain amount of temperature was desirable in fevers, his practice was not to reduce it in typhoid fever below 101°. Extreme care should be exercised in using the bath in the third week of

typhoid, even though the temperature remained high and the bath seemed to afford relief. Rarely did he give the bath more than three times in the twenty-four hours in the third week of the disease, and often it was better to give only one bath in this period. Where the patient was advanced in years, special caution was necessary if a bath were used at a temperature below 80°. Here it was often better to resort to sponging, or the use of a wet-pack at 80° applied anteriorly from the neck to the knees. He agreed with those who believe that hemorrhage and peritonitis are contraindications.

Constipation.—Dr. Smith said that he favored the giving of calomel once or twice during the first few days of typhoid fever, as it seemed to add to the patient's comfort. He did not repeat this mercurial, however; but if constipation were present, made use of a mild saline cathartic or of liquid cascara. After the first eight or ten days, he did not believe it was wise to give cathartics at all in the treatment of typhoid fever, and hence if constipation continued he made use of enemata until the patient had had a practically normal temperature for at least ten days.

Intestinal Antiseptics.—He did not believe intestinal antiseptics accomplish anything in the way of modifying the duration of the disease, but they certainly add to the patient's comfort. He ordinarily employed salol, betanaphtol, or carbolic acid, or else some preparation of creosote.

Intestinal Injections.—He had tried intestinal injections, and had not found that they accomplished much more than adding to the patient's discomfort, and he was inclined to believe that they tend to cause hemorrhage or even intestinal perforation.

Coal-Tar Products.—He did not fear to use the coal-tar products in the first week of typhoid fever, provided they were given in small doses and were guarded by aromatic spirits of ammonia. His personal preference was for phenacetin, given in doses of five grains two or three times a day. He did not use them to reduce temperature, but solely to increase the patient's comfort, and he did not prescribe them after the early part of the second week. Where wakefulness was a troublesome symptom, he had found that ten grains of trional or sulphonal, combined with not more than $\frac{1}{12}$ of a grain of morphine, often gives very restful sleep.

Stimulants.—His own custom was to use alcohol if there were distinct indications for its use. He recognized as those indications, in an adult, a pulse of 120 or over and feeble, particularly if irregular, intermittent, or variable in its rapidity; brown, dry, and fissured tongue; low muttering delirium. Ordinarily, a case of typhoid fever does not require alcohol until the third week. In alcoholic subjects, it must, of course, be pushed more than in others. Of the other heart stimulants, he made use of strychnine, caffein, and camphor, his preference for them being in the order named.

Intestinal Hemorrhage.—He did not depend upon any medicament to secure a specific effect in controlling intestinal hemorrhage, but relied upon absolute quiet of the patient and the use of some preparation of opium to check peristalsis. The application of ice to the abdomen, in his opinion, accomplishes no good and possibly favors hemorrhage by driving the blood from the surface to the viscera.

Diet.—The typhoid-fever patient should receive water freely—four ounces at a time, six times daily. Bouillon or strained broths, if well salted, would often prove very grateful to the patient. Where milk is very repulsive to the patient, broths can be used with the addition of the whites of several eggs daily. He had not seen any harmful result from such practice. A very common error was to give the typhoid-fever patient altogether too much milk. His own custom was to adhere to a practically fluid diet for eight or ten days after the temperature had practically reached the normal, and he considered this of the greatest importance. He had at times tried a more liberal diet, and almost always with disastrous results. He did not believe that diet has the power of itself absolutely to cause a relapse, but recrudescence and disturbance of digestion, and the occurrence of intestinal hemorrhage and even perforation seemed to him to be favored by the too early resumption of a liberal diet.

Signs of Impending Perforation.—Dr. Francis P. Kinnicutt opened the general discussion. With regard to the perforations of typhoid fever, he said that Cushing of the Johns Hopkins Hospital had called attention to what he named the pre-perforative stage of typhoid fever. The symptoms of this stage are chiefly abdominal pain and tenderness and leucocytosis. It would be generally admitted, the speaker said, by physicians that subjective abdominal symptoms, such as abdominal pain and tenderness, are the exception in typhoid fever, and hence, if present, they should always excite attention and arouse a suspicion of impending perforation. A marked leucocytosis in typhoid fever usually indicated some serious complication. A sudden leucocytosis, in the absence of other appreciable cause, if associated with abdominal pain and tenderness, should excite a strong suspicion of impending perforation. There was, however, another sign sometimes present, and which he had been able at times to detect and demonstrate to others—he referred to a localized, fine peritoneal crepitation in all respects similar to that obtained in cases of inflamed pleura or pericardium, and produced in an exactly similar way. It could be sometimes heard with great distinctness if the abdominal respiratory movements had not been arrested. The appreciation of such a sound necessitated a very careful auscultatory examination of the entire abdomen. In cases of general peritonitis, before the abdominal respiratory movements had been largely arrested, it was a sign which would often be elicited if carefully searched for. Of course, the sign would not always be obtained, because the abdominal respiratory movements might be arrested. Again, it must be remembered that a fatal peritonitis may occur in typhoid fever without any recognizable perforation. He quite agreed with Dr. Smith as to the feasibility and advantages of the bed bath. It was used in the Massachusetts General Hospital to the exclusion of the ordinary tub. The only disadvantage was that the water does not cover the entire body. It was used in the Presbyterian Hospital of this city, though not to the exclusion of the tub bath. Where it was employed, the anterior surface of the body was kept wet by the use of a watering-pot and sprinkler. Perhaps another disadvantage of the bed bath was that one loses some of the good effect resulting from friction. He had made use of ichthoform, a combination of ichthyol and formaldehyde, a tasteless powder which is easily taken and is a very efficient antiseptic.

Diet Should be Varied.—Regarding diet, he would say that he thought a more varied diet than that obtained by the administration of milk alone was desirable. He would not give a diet less easily digested, but he thought one could give a more varied diet that is just as easily digested as milk. His rule was to vary it as much as possible. His patients get milk, a little chicken or mutton broth, barley water, oatmeal water or rice water, junket, and custard. The oatmeal water is of the consistency of cream and is made by boiling half an ounce of oatmeal in eight ounces of water and straining it. He also made use of beef peptonoids, for he had seen no harm from this, and many patients were unable to digest milk in any form.

Cases Without Widal Reaction.—Dr. N. E. Brill said that he had had an experience in the last few years with a group of seventeen cases presenting the clinical picture of typhoid fever. These had occurred in the summer of 1897. The only dissimilarity clinically between them and ordinary typhoid fever was that they were not of the customary four weeks' duration. There was the usual loss of appetite, the chill or chilly sensations, and the headache.

In a large proportion of the cases, the roseola and the enlarged spleen had been present. Examinations for the Widal reaction had been made daily, yet in none of them had this reaction been positive. Other cases in the hospital at the same time constantly gave the reaction. In a number of cases, cultures had been made from the blood procured from the spleen, and colon bacilli had alone been obtained. The experience with these cases suggested the notion that typhoid fever may result from infection with a variety of similar bacilli. Among the unusual complications of typhoid that he had encountered were otitis media and central deafness.

Dr. FRANCIS W. MURRAY said that as the great majority of cases of intestinal perforation are doomed without surgical intervention, the surgeon should be called in as soon as possible after the occurrence of this accident. The appendicular form constitutes the smallest proportion of these cases. If the operation were undertaken uniformly within the first eighteen hours, the mortality should be much better than it had been hitherto. He was under the impression that at the present time the percentage of recoveries varied between thirteen and twenty-four. Among the surgical complications that he had met with were infections of the bone and periosteum, and abscess of the parotid.

Dr. ABBÉ said that the average statistics for operations on cases of typhoid perforation in the first twenty-four hours after the accident gave 26 per cent. of recoveries, but Dr. W. W. Keen had found that the group of cases operated upon between twelve and eighteen hours after perforation gave 32 per cent. of recoveries. He wished to emphasize the fact that the uninflamed peritoneum is not sensitive or the seat of pain, and hence the importance of the subjective abdominal symptoms referred to by Dr. Kinnicutt. This was well shown when the peritoneum is handled in abdominal operations done under cocaine anæsthesia.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, November 25, 1901.

FRANK VAN FLEET, M.D., PRESIDENT.

Address of Retiring President.—Dr. GEORGE G. FOWLER said that in 1807 the Medical Society of the State of New York had been organized at Albany, and that very early in the history of this society a liberal code of ethics had been established. About 1850, the doctrine of Hahnemann had been promulgated, and one of his emissaries coming to this country, two or three members of the Medical Society of the State of New York essayed to test these new therapeutic methods. As a result, these gentlemen had been promptly expelled, and this act had led to an increase of homœopathy and the formation of a homœopathic society. As time had gone on, it had been found that the teachers and many of the other great lights of the profession were consulting with homœopaths. This practice had led to a great upheaval in 1880, and a determination to overthrow the old code of ethics and allow of more liberal relations between all sorts of practitioners of medicine recognized by law. The result of this movement was that to-day the members of the society consult with any legally qualified practitioner. This had been largely brought about through the efforts of Dr. D. B. St. John Roosa, and it had been the means, the speaker declared, of raising the standard of medical education beyond all expectations. At the time of this great movement, there had been a few left over who still adhered to the old-fashioned and less liberal notions, and who formed the New York State Medical Association. They had not amounted to much, however, for many years; but within the last few years they had been very much in evidence. Dr. Fowler said he trusted he was right in saying that there are agencies at work to-day which would result in bringing harmony out of discord and doing away with all such factions. He hoped the day was very near when they would be done away with, and there would be a general handshaking and a uniformity of opinion regarding what should be our actions. In conclusion, he expressed the hope that scientific medicine would still be the chief object of the society's work, and that in the near future the whole medical profession would be one. Dr. Fowler then introduced his successor in office, Dr. Frank Van Fleet.

Address by the President-Elect.—Dr. FRANK VAN FLEET gave an outline of the work proposed for the ensuing year. He said that at the present time the membership of the society amounts to nearly 1,700, and that the society aims to include in its membership all reputable practitioners of medicine who are willing to assert that they practise no exclusive system. The County Society is not a club, and membership should not be denied to any one merely because of a personal dislike. Every physician who is eligible is under a moral obligation to become a member. The speaker said that he should endeavor to increase the membership of the society, protect the community by the enforcement of the medical laws, secure creditable scientific contributions and discussions, and aim to promote more friendly feeling with the outside forces at the present time antagonistic to this society.

Prosecution of Illegal Practitioners.— The cost of securing convictions of illegal practitioners of medicine was considerable. A few years ago, it had cost the society about $145 for each conviction; last year it had cost $79 per conviction, and the average for the past seven years had been $96. Of course, this was not the net cost; after deducting the fines collected, the cost amounted to about $22 for each conviction. The average cost of maintaining the legal department had been $250 per month, and even allowing for the collection of fines and every proper economy, it must average at least $50 per month. It was proposed at each monthly meeting to discuss one particular subject.

Overtures to the County Medical Association.—Regarding the next topic, the speaker said he approached it with some hesitation. His avowed object was to "promote a friendlier feeling between ourselves and forces now antagonistic to us, to the end that our sphere of usefulness may be increased, and that we may be a thoroughly united profession." It had come to him from various unofficial sources that the American Medical Association had been reorganized so that the question of the code does not now receive official recognition. If this information were correct, there would be reason to believe that the American Medical Association would gladly receive delegates from the County Medical Society, and he would recommend that the State Medical Society take suitable action in these premises. He firmly believed that there should be reciprocity among the State examining boards throughout the United States, and that there should be a national bureau of health, with a physician at its head who is a member of the cabinet. Such objects could be best attained by means of a national medical organization; and as the American Medical Association was at present in the field, it was most desirable that this body should thoroughly represent all of the medical profession of the United States. Dr. Van Fleet said that a person high in the councils of the American Medical Association had written to him as follows: "Nearly all of the States have followed yours with reference to the laws relating to the practice of medicine, and in nearly all of these States the State medical examiners violate the code of ethics by signing diplomas of members of other medical schools." There should be, Dr. Van Fleet said, some common ground upon which the advocates of both organizations might get together and determine what, if anything, could be done. He would recommend that the Medical Society of the County of New York appoint a committee

to ascertain if the amalgamation of the two organizations cannot be effected, and that this committee report to the society in January, or sooner. He was not one of those who believe in rejecting overtures of peace; he would even present the olive branch to colleagues in other organizations which had been opposing them, and would exhaust every honorable means to bring about a reconciliation; but if their efforts were spurned, they, of this society, venerable in years and honorable in reputation, must go on in their own way.

Dr. D. B. St. John Roosa then rose and offered the following resolution in accordance with the recommendation of the president, and it was unanimously adopted.

Resolved, That the President of the Medical Society of the County of New York appoint a committee of five, of which he shall be chairman, provided a similar committee be named by the New York County Medical Association, to confer with that body with reference to the union of the two organizations; and that this committee be requested to report to the society at the stated meeting in January, 1902, or sooner, in order that this society may, if desirable, make a recommendation to the Medical Society of the State of New York at its next annual meeting.

Report of the Committee of Seven on the Prophylaxis of Venereal Diseases in this City.—This committee consisted of Drs. P. A. Morrow, Chairman; Ludwig Weiss, Secretary; C. W. Allen, L. D. Bulkley, H. D. Chapin, E. D. Fisher, and S. A. Knopf. Dr. Morrow presented the report of this committee in abstract. A circular letter asking for information concerning the statistics on venereal disease from private practice had been sent to every physician in New York County. This had elicited 886 replies, or nearly 20 per cent. Of this number, 208 replied that they did not keep sufficiently full and accurate records to be of any value to the committee. Eliminating the more indefinite replies, it was found that about one physician in seven had furnished statistics which could be made the basis of study. The statistics thus obtained yielded an aggregate of 23,106 cases of venereal disease reported by 678 physicians, 15,096 being gonorrhœa and the rest syphilis. It was reasonable to believe that an equal number of cases of venereal disease had been treated by those who had not replied to the circular, so that it was probable that over 100,000 cases of gonorrhœa and syphilis had been treated during the past year in private practice. A study of the statistics referred to indicated that about 40 per cent. of the women suffering from gonorrhœa had pelvic complications. It also showed that about 60 per cent. of the syphilitic women had been infected by their husbands. From the 37 dispensaries allowing their records to be inspected by the committee, it was found that during the past year there had been treated at these institutions 13,010 cases of gonorrhœa and 7,007 cases of syphilis, or a total of 22,250 cases of venereal disease. To this should be added 0,542 unclassified cases of venereal disease. The records of the hospitals show cases of locomotor ataxia, monoplegia, hemiplegia, and various other affections, in which syphilis is known to be a prominent factor. The committee estimated that in Greater New York there had been treated in one year, in both private and public practice, a grand total of 225,000 cases of venereal disease. There had been no disposition on the part of the committee to swell the figures, and the work had been greatly hampered by the lack of system and of a uniform nomenclature employed in the keeping of institution records. It should be noted that officially venereal diseases do not exist in New York City.

Mortality. Speaking of the mortality from venereal disease, either directly or indirectly, the report very justly asks why it is that the Board of Health should concentrate all its forces and make use of its expensive equipment to stamp out smallpox, which caused only a few deaths in this city last year, while it ignores "the great pox."

The Remedy. It was by no means clear, said the speaker, that the regulation of prostitution has reduced venereal disease in the countries where it has been employed, and the committee did not recommend its adoption here. Of the replies received, 203 recommended segregation of prostitutes, but the committee did not deem it wise to recommend this at the present time. The vigorous enforcement of the new tenement-house law would doubtless result in ejecting a large number of public women, and from a common-sense, as well as a humanitarian, point of view, it must be admitted that these unfortunates must have some habitation. The most feasible plan seemed to be to compel all prostitutes to inhabit houses by themselves. This domiciliary separation should be absolute and complete. No new legislation was needed to accomplish this result, but rather a relaxation of the law regarding prostitution *per se*. If left to itself, prostitution would naturally confine itself to certain quarters of the city, following the lines of least resistance, and this plan seemed best to subserve the interests of the public. In this scheme, the function of the police would be merely to preserve order and decency, and would take out of their hands the power of levying tribute. All red lights and other external and visible signs of prostitution should be rigorously banished. Venereal diseases, like other contagious diseases, are already under the control of the Board of Health, though this board does not officially recognize them. The first step, therefore, should be to awaken this board to a sense of its responsibilities in this matter. The committee was not prepared to formulate a system of control complete in all its details, and the committee did not recommend the placing of venereal diseases among those to be reported to the Board of Health, though all hospitals and dispensaries should be required to report all such diseases. If public sentiment supports the Board of Health in imposing a heavy fine for spitting upon the floors of public conveyances, surely, it would sustain a law penalizing the transmission of syphilis. The latter is a crime against society, and its responsibility for the spread of disease should be narrowed down as far as possible to a question of individual responsibility, chiefly in the interests of minors. A law raising the age of consent would be an additional safeguard. Prostitutes of minor age, when detected, should be sent to a reformatory and detained there until the age of twenty-one. The business of procuring young and innocent girls for introduction into a life of shame was a crime having hygienic as well as moral aspects, and the law should punish this class most severely. In the opinion of the committee, education and treatment promise the best means of immediate relief. Education should begin in the ranks of the medical profession, the study of venereal diseases being made an essential part of the training of every student of medicine. Those charged with the education of young men in high schools and colleges should instruct them as to the dangers of licentious living, and should combat the theory that such indulgence is necessary to health. The most effective means of preventing the spread of venereal disease is by prompt and efficient treatment. Every case of venereal disease should be looked upon as a possible focus for the spread of the disease. The number of infections that had been traced to a single source was most remarkable. The committee recommended that every general hospital, receiving stated municipal assistance, should be required to open its doors to venereal cases. Fortunately, most patients of this class can be properly treated in dispensaries. The committee did not recommend any specific legislation for the control of prostitution, because of the firm conviction that the State is powerless to control this evil.

Dr. Ferd. C. Valentine said that history showed that prostitution naturally tends to segregation, for, in this city, until an effort had been made to scatter the prostitutes, they had been pretty strictly located in certain districts. He approved of domiciliary control, and sug-

gested that in a port like New York City it would be well to have circulars of information printed in various languages and distributed freely through these districts.

Dr. JAMES PEDERSON said that it was not so easy to reach and educate adults, as it was to educate the juvenile portion of the public. It was the province of the family physician to give wise council on this subject, and it was wholly within his power to impress upon men, through their fathers, the seriousness of venereal disease.

Dr. S. A. KNOPF moved that the society take into consideration the establishment of a prize for the best popular essay on the means of preventing the dissemination of venereal disease. Seconded by Dr. George B. Fowler and carried.

Dr. B. LAPOWSKI expressed the opinion that one of the great obstacles to the prevention of the spread of venereal disease was the public's over-confidence in the power of the medical profession successfully to treat these diseases. For example, in Berlin, there is 1 prostitute to 400; in Paris, 1 to 909, and in Breslau, 1 to 365; yet in Breslau, where Neisser himself has much to do with the inspection of the prostitutes, venereal diseases are especially prevalent, the people feeling confident that there can be no danger where the inspection is made by so great an authority.

The Committee of Seven was continued, and a vote of thanks was given to them for the excellent manner in which they had performed their arduous duties.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 5, 1901.

JOSEPH COLLINS, M.D., PRESIDENT.

Portrait of Dr. E. C. Seguin.—Dr. J. ARTHUR BOOTH presented to the society a portrait of one of the founders of the society, the late Dr. E. C. Seguin. The portrait was donated by Mrs. Seguin.

A Case of Disseminated Sclerosis.—Dr. WILLIAM M. LESZYNSKY presented a man whom he had first seen about two years ago. At that time he was thirty-two years of age, and stated that he had been well up to eighteen months previously. At that time he had suffered from occasional diplopia, but it had since almost disappeared. He had had occasionally a staggering gait and speech had become slow. There had also been some difficulty in swallowing. There had been no headache, tinnitus, or vomiting, and no bladder symptoms. When first seen, he had complained of being nervous and emotional. The examination showed him to be healthy in appearance. There was slight hesitancy in speech, and he was disposed to break into tears on slight provocation. There was slight horizontal nystagmus on efforts at fixation. The fund and the visual fields were normal. His gait was slightly ataxic, and there was slight dragging of the right leg and a tendency to fall to that side. Both knee-jerks and Achilles reflexes were exaggerated. The examination of the urine was negative. On January 23, 1900, there was slight paresis in the left posterior thigh muscles and slight ataxia in the left upper extremity. In May, it had been noted that he was not so emotional, but he dragged the left leg in walking and right hip, and the scapulæ were prominent. In December, it had been noted that the static ataxia was well marked. In March of the present year, there was slight rigidity and dragging of the right leg in walking, with tendency to fall to the right. At the present time the pupils are normal, there is slight oscillation of the eyeballs; slight ataxia of the right upper extremity, muscular power is perfect; the speech is slow and uncertain; there is a tendency to fall toward the left, with a paraplegic gait. He stands with difficulty on either leg alone. Both knee-jerks are equally exaggerated. A specimen of his handwriting was exhibited. During the past year, there had been practically only an increase in the cerebellar incoördination and in the defect of speech. The man presented none of the stigmata of hysteria, and was in no way neurasthenic. While he did not present all of the characteristics of disseminated sclerosis, there were sufficient symptoms present, the speaker thought, to warrant this diagnosis.

Dr. B. SACHS thought there could be no doubt about the correctness of this diagnosis. It seemed to him a good example of the rather rare cerebellar form of multiple sclerosis.

Tumor of the Pons.—Dr. JOSEPH COLLINS presented some sections from a tumor of the pons. They had been taken from a woman, about forty years of age, who had gone to a dance on August 24, 1900, feeling quite well. After dancing a short time, the evening being very hot, she fell over and remained unconscious for two hours. She said that her head felt heavy and her feet very light. The next morning, on attempting to do housework, she found that she was very dizzy, and that the left side of the body did not seem to be under proper control. During the next three weeks, there had been three transitory attacks of unconsciousness. There was, in addition, pronounced ataxis of the extremities, but no paralysis. There was also constant vertigo with occasional vomiting, and a feeling of great weakness. She also suffered from a distressing diplopia. After an interval of about a week, during which the symptoms had abated, they had again returned. She had then exhibited inebrious speech, and had suffered from nausea on the slightest movement. He had seen her about seven weeks after the original attack, and examination had revealed paralysis of the right abducens and of the right facial, with no reaction of degeneration, slight anæsthesia of the upper two branches of the fifth nerve, with no involvement of the lower branch; also hemiataxia and an exaggeration of the tendon-jerks all over. There was not much headache at the time, and no optic neuritis. The woman died with symptoms of bulbar involvement. The lesion had been diagnosticated as an acute softening in the left half of the pons. On autopsy, a section through the pons revealed a fluid mass, but no evidence of a tumor or of an increase in the consistency of the pons. It had only been after hardening and cutting the pons that it had been found that there was an enormous angiosarcoma involving the left etage of the pons. It had pushed over the raphe and infiltrated the right half of the pons as well. The explanation of the lack of symptoms that one would expect with such a condition was that the growth had infiltrated between the motor and sensory fibers of the pons, but had failed to destroy them until a short time before the death of the patient. This was entirely at variance with what was usually observed in a growth of this character. Both acoustic nerves had escaped. At no time had there been any disturbance of vision, though careful tests had been made to determine the point.

Dr. M. ALLEN STARR said that last March he had seen, in consultation with Dr. Biggs, a patient who had presented a rather similar set of symptoms, namely, diplopia and paresis of several of the ocular muscles on both sides without a typical ophthalmoplegia externa. The patient also had anæsthesia of one side of the face, and had the kind of speech often observed in bulbar palsy, together with a marked ataxia. There was no choked disk, so that the question had arisen as to whether the condition was one of softening or tumor. In the absence of headache and choked disk, he had inclined to the diagnosis of softening, but the autopsy had shown an infiltrating glioma.

Clinical and Anatomical Report of a Case of Multiple Congenital Deformities.—Drs. B. ONUF and J. FRAENKEL presented a joint paper, which was read by Dr. Fraenkel. The subject of the report was a girl who, at the age of four years, had been admitted into the Montefiore Home on September 22, 1895. The condition of the extremities had been noticed immediately after birth, and it was said that convulsions had occurred frequently during the first

year. One year and a half before admission, an osteotomy had been done at the hospital for clubfoot. During her stay in the Montefiore Home, the girl had been frequently examined by various specialists. The child showed normal cerebration, but the emotions were displayed in an explosive manner. The chief features were: Motor disturbance of all four extremities; asymmetry of facial innervation, the face being drawn to the left; atrophy of the muscles of the forearm and fingers, drop-wrist on both sides; decided diminution in the motor power of forearms and hands; absence of the reflexes of the upper extremities; lower extremities decidedly tapering, and the right one the longer; decided diminution of the motor power of the flexors of the leg and extensors of the foot. On attempting to walk, or standing erect, an intense lordosis developed, and there was a cock-step gait. The clinical picture had remained practically unaltered up to the time of her death from diphtheria in June, 1897. The autopsy had been made by Dr. George R. Elliott. There was a subluxation of the hand and forearm forward. The palmaris-longus muscle was absent. The ulnar half of the flexor sublimis digitorum was much reduced in volume, while the radial half was composed of fat only. The flexor pofundus digitorum was also quite fatty. The flexor longus pollicis was converted into fat and the supinator longus into a band. The muscles of the extensor side of the forearm were all small, but were not fatty. The thenar muscles were absent, with the exception of the flexor brevis pollicis. There was a dislocation of the left hip upward and forward, without any break in the capsule, and the head of the bone was situated forward of the natural acetabulum. The new acetabulum was made up of the thickened capsular ligament, but was otherwise apparently normal in shape. The pelvic and thigh muscles on the side of the dislocation were either fatty or atrophic. Microscopical examination of the psoas and entire muscle mass of the three adductors demonstrated: (1) A reduction in the volume; (2) An increase in the perimuscular fat tissue in some, and interfascicular fatty tissue in others, at the expense of the muscular tissue proper; (3) Increase of the perimuscular fat, chiefly in the adductor group of the left thigh; (4) Increase of the fibrous connective interstitial tissue; (5) A vascular change, chiefly a thickening of the vessel walls; (6) Disintegration of muscle fibers in some muscles; (7) Preservation of a relatively large number of muscle spindle-cells in the affected muscles; (8) Changes in the intermuscular nerve bundles, chiefly a scarcity of the nerve fibers, and thickening of the perineurium. No less than forty-four spinal nerve-roots were examined microscopically, and changes were found, not only in many anterior, but also in many posterior, roots. The spinal cord, on gross examination, showed an unusually meager development of the cervical and lumbar enlargements. Microscopically, there were noted: (1) A shrinkage of the nerve cells of the anterior horns in most levels of the spinal cord; (2) A shrinkage of the cells of Clarke's columns in certain levels; (3) Vascular changes and cavities in the gray matter, chiefly in the cervical and dorsal regions; (4) The presence of apparently undeveloped cells at certain levels; (5) Proliferation of the ependyma of the central canal in certain regions; (6) Changes in the white matter, probably by artefacts. On gross examination the brain exhibited nothing peculiar. Changes of an atrophic order, and apparently the presence of certain cells in an embryonic state, were noted on microscopic examination. The cells most frequently affected were the larger pyramidal cells. No vascular changes were noted. The authors concluded that in this case the primary cause of the muscular changes, and incidentally of the deformities, was either a poliomyelitis or a central neuritis of prenatal origin. The cortical changes were thought to be secondary to the spinal changes. To give some idea of the minuteness and exhaustiveness of the examination made of this case, it should be noted that 5,500 sections were made and prepared for examination.

Dr. GEORGE R. ELLIOTT presented the right forearm and pelvis of this child, and demonstrated some of the muscular peculiarities noted in the report. The head and shaft of the dislocated bone, he said, were normal, except that they were small from disuse. The dislocation was upward. The speaker emphasized the fact that this was not the form of dislocation known as a congenital dislocation of the hip; true congenital dislocation of the hip was almost invariably backward on the dorsum of the ilium. The large ligamentum teres seemed to be only a physiological hypertrophy. There was nothing in the drop-wrists to warrant them being called congenital dislocations; they were rather the result of the pareses. With reference to the peripheral theory, Dr. Elliott said he could not quite understand how this would explain the picking out of portions of muscles and having them replaced by fat, while others remained absolutely normal.

Dr. B. SACHS said that, having seen the child during life, he had never doubted that the diagnosis lay between an intrauterine poliomyelitis and a developmental defect. The paralytic conditions were secondary to the central change. In spite of the elaborate investigation that had been made, the report was not wholly satisfying as to the character of the process. It did not seem to him that developmental defect of the gray matter of the cord could not be excluded by the findings reported. It would have been interesting to follow up the anterior spinal artery and determine if this vessel were properly developed, and had functionated properly. If it had not been normal, almost all of the changes in the gray matter described in the report could have been easily explained in that way. The case seemed to him to offer an example of a possible arrest of the development of the gray matter of the cord. He would like to know whether any unobjectionable case of intrauterine poliomyelitis had been reported.

Dr. V. P. GIBNEY said that, so far as he knew, this was the first case of intrauterine poliomyelitis that had been reported. In various discussions on clubfoot, the subject of intrauterine poliomyelitis had been pretty effectually disposed of. He agreed with Dr. Elliott that the dislocation in this case was not a true congenital dislocation of the hip.

Dr. JOSEPH COLLINS said that, judging from the report, he would not be satisfied to admit that the case was one of infantile poliomyelitis, because nothing had been said regarding the changes in the substance of the cell as evidence that these cells had undergone the parenchymatous changes which cells do suffer in poliomyelitis of every kind. He understood that the reason these changes had not been described was because the specimens had not been properly hardened for the Nissl stain. This was a great obstacle to the acceptance of the statement that the lesions were dependent upon a poliomyelitis. In poliomyelitis of every kind the external contour of the cord does not change, yet in the case reported shrinkage of the cord was prominent. Again, the cells were reported to be quite scarce, but the cells themselves were not materially disintegrated as should have been demonstrable in specimens so prepared. He found it impossible to imagine that this perceptible decrease of cells in size and shape in the motor region was purely secondary to the smallness of the cells in the cervical and lumbar regions. The changes in the muscles seemed to indicate very distinctly that they were secondary to central changes.

Dr. B. ONUF closed the discussion. He said that he thought that even if the anterior spinal artery had been badly developed, it would not explain why the changes observed were so much more marked in some regions than in others. Again, the intramuscular nerve bundles appeared degenerated. If there had been a developmental defect in the spinal cord, one would look for absence of

certain nerves and expect the rest to appear normal. In his opinion, the changes found in this case were fairly typical of poliomyelitis. The number of the cells appeared, on the whole, to be diminished. If this were a case of intrauterine poliomyelitis, it was probable that comparatively few lesions would be found so long afterward as evidence of the process that had taken place. The changes of contour were probably explicable also on the ground that the process had lasted so long. The distribution of the cell changes was far from being uniform. He saw no reason why the cortical changes should not be looked upon as secondary in view of the fact that the process must have occurred very early in life. In cases of congenital porencephalus of the right occipital lobe, marked atrophy of the optic nerve had been observed and reported. In a case of this kind, it was not right to draw conclusions from one or two points, but only after a careful study of the whole picture.

The Finer Microscopic Structure of the Cortical Areas in Man and Some Mammals.—Dr. M. G. SCHLAPP made some remarks on this subject. He said that he had been struck with the great differences in the descriptions of the cortex as given by different writers. The earlier authors described five or six layers in the occipital lobe, whereas more modern writers described eight or even nine layers. These discrepancies he would explain by the fact that different animals had been used for their observations. The higher one goes in the animal kingdom, the more the philogenetic secondary center tends to replace the philogenetic primary center. The secondary center does not control all movement, however. Plates were exhibited to show the differences in different animals. The motor area is not developed in the lower animals, so that it can be distinguished from the rest of the cerebrum; but such an area can be observed in the dog and in the monkey. In the dog, it is very near the frontal pole, whereas, in the monkey, it is much further back. In the monkey is found an eight-layer structure. The cortical sight center is very much developed in the monkey and in man. These differences in structure were demonstrated under the microscope. The granule cells are characteristic of a highly developed cortex. Most of these cells have ascending axons or very short axons. They are the cells which receive the impulses. These cells are very much more developed in the sensory than in the motor areas. In the sight center is found the eight-layer type. The auditory center can be recognized, but is not so sharply distinguished as is the sight center.

Rumination in Man.—Francesco Cascella reports a case. He reviews the various theories held on the subject, and concludes that, whether the habit is a morbid symptom or whether it is merely a reflex phenomenon which, by constant repetition, becomes a perversion of the digestive function, it is always the expression of an atavistic functional phenomenon. It is oftenest seen in persons who possess other signs of degeneration, as was the case with the patient described by the author. *La Riforma Medica.*

Leucocytosis from Digitalis.—Alessandro Gazza has found by experimentation on rabbits that the injection of a non-toxic dose of digitalis determines a leucocytosis. Digitalin and digitoxin produce an even greater effect. The leucocytosis lasts several days. If the digitalis be pushed to lethal doses, the number of leucocytes increases to the end. Further experimentations have proved that the digitalin leucocytosis greatly retards the death of rabbits infected with pneumococci. Those experimented upon died on an average at the end of 112.53 hours, while the "control" animals died in 44.15 hours. The author concludes that the administration of substances capable of causing leucocytosis is a valuable means of treatment in pneumococcæmia.—*La Riforma Medica*

New Instruments.

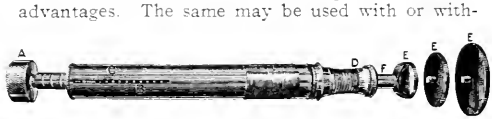
A NEW PERCUSSION MALLET.

BY HEINRICH STERN, M.D.,
NEW YORK.

FOR various purposes we possess instruments of precision which have replaced the more ancient clinical devices and appliances. However, in percussion, whether we employ finger, finger-pleximeter, or hammer-pleximeter percussion, we make use of rather primitive methods. The employment of the clinical thermometer, for instance, a standardized instrument, precludes all uncertainty as to the temperature of a patient. Percussion by the older methods, on the other hand, is solely dependent upon the skill of the individual practitioner. It is an art in which some excel and a number are quite efficient, but which the great majority of physicians employ in an indifferent and superficial manner. This indifference for and neglect of one of our foremost diagnostic means, I think, may be ascribed to the rather inexact methods which are still in vogue.

A standard percussor should exhibit the followlowing features: (*a*) The stroke should be uniform in intensity and duration. (*b*) The intensity of the stroke should be measurable and controllable, according to position and size of the organ to be examined. (*c*) The percussor should elicit the physical condition not only of parietal organs, but also of deeper-lying structures, if it be so desired.

I have devised an instrument possessing these advantages. The same may be used with or without plexímeter. The automatic dental plugger has served me as a model in constructing my percussor.



The instrument is made of metal and hard rubber. It represents: (*a*) Pressure regulator; (*b*) Hammer spring; (*c*) Pressure index; (*d*) Return spring; (*e*) Plexímeter disks, or pressure transmitter; (*f*) Sliding mechanism. The pressure regulator winds and unwinds the spring which impels the hammer. The hammer spring, unwound to a certain degree, still exerts a pressure equivalent to 100 grams; if wound up, its pressure capability amounts to 2,500 grams. The pressure index is graduated accordingly. The scale denotes a pressure of 100, 250, 500, 1,000, 1,500, 2,000, and 2,500 grams. The return spring facilitates the return of the sliding mechanism into its working position. The plexímeter disk is that part of the instrument which comes in immediate contact with the individual to be examined, and acts therefore as a clinical pressure transmitter. The hammer itself, springs, and other parts of the mechanism are encased in a metal or hard-rubber tube.

Any ordinary plexímeter will suffice if the instrument is to be used for mediate percussion. However, the plexímeter disk at the contact point of the hammer makes an additional plexímeter superfluous. In mediate percussion the smallest plexímeter disk is the one to be preferred. In performing immediate percussion, skin and subcutaneous tissues should be moderately stretched by the index finger and thumb of the left hand. The hard-rubber plexímeter disk having been attached to the sliding or movable part of the instrument, is now

firmly applied to the portion of the body to be percussed. The instrument is held between the thumb and the middle and index fingers of the right hand. If deeper-seated organs are to be examined, that is, if great pressure has to be exerted, it is best to have the pressure regulator rest against the palm of the hand. The pleximeter terminus being in a fixed condition, the hammer part is pressed toward it. Thus the individual to be examined in reality receives an indirect stroke. The sounds elicited by this mode of percussion do not materially differ from those obtained by the old method of striking. However, the uniformity of the stroke and the subsequent homogeneousness of the oscillations as obtained with this percussor can never be secured by the older means.

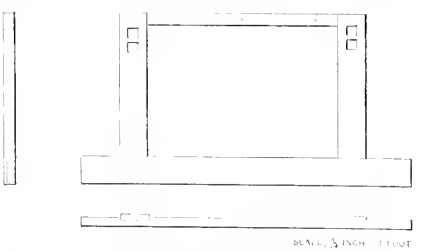
This is the first instrument by the aid of which rational percussion is possible. The inexperienced practitioner who wishes to employ this instrument has merely to train his sense of hearing, and not his fingers, and by the use of the percussor he is enabled to recognize and to locate many physical abnormalities with a similar degree of certainty as he determines the patient's temperature by the clinical thermometer.

56 East Seventy-sixth Street

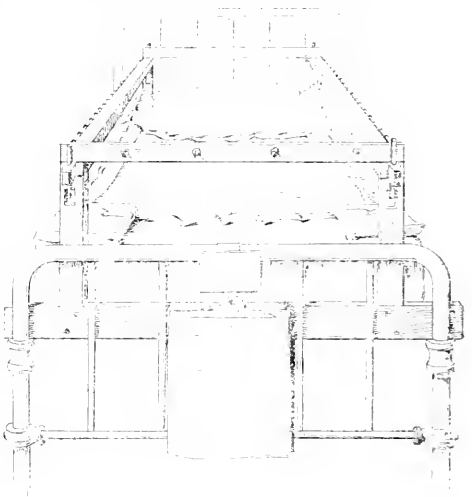
A FRAME FOR THE TYPHOID SLUSH BATH

By U. F. Martin, B.S., M.D.
New York

For some time past it has been the custom in the medical wards of St. Luke's Hospital of this city to carry out the Brandt method of treatment of typhoid fever by means of a slush bath. In this way the patient was saved the strain of lifting in and out of the tub, and, in our experience, about the same lowering of temperature was secured. The construction of the trough for the water was, however, quite troublesome, and not always satisfactory. It consisted in rolling up blankets and laying them around the edge of the bed, and then, by putting a rubber sheet under the patient and over the blankets at the edge of the bed, a trough was formed of sufficient depth to permit the patient to be about half submerged. The slushing process then went on, the cooling of the water being obtained by means of ice floating as in the tub.



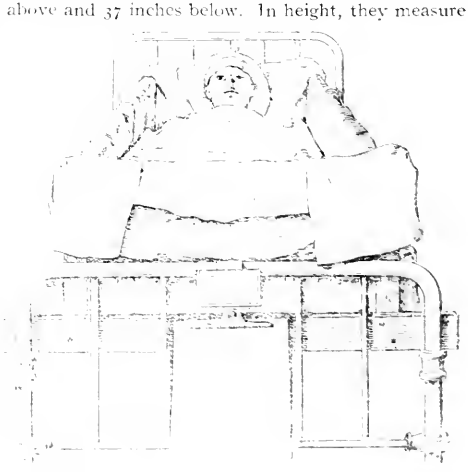
The disadvantages of the scheme were the awkwardness of the arrangement, the ease with which the bed sheets were wet, the inability to submerge the patient more than half, the difficulty in pouring the water in and out, the drying of the blankets used in making the trough, etc. To obviate some of these disagreeable features, an effort was made to secure some suitable frame, simple in construction and easy in manipulation, that might be placed on the bed to take the place of the less cleanly blanket frame. After more or less discussion among those interested,



the following has proved to be a practical and valuable means of carrying out the slush bath.

Because so many who have seen the frame in use have expressed their approval and desired a drawing of the same, it was thought that, although not altogether new, it might be helpful and suggestive to many, applicable as it is even in private practice.

The frame can be made of any kind of light wood, for it sustains practically no weight, being used simply to attach the rubber sheet. As seen in the illustration, which is drawn approximately to scale of one inch to the foot, it consists of four pieces, the two end-pieces and the two bars. For the ordinary hospital bed, the end-pieces measure across 27 inches above and 37 inches below. In height, they measure



10½ inches, the holes for the bars to fit in being placed at different levels, to permit change in the depth of the trough. The bars are equal to the length of the

bed, or about 6 feet 7 inches, their thickness being unimportant. The part which projects through the end-pieces has a small opening in which are inserted wooden pins; in use the pins have not been found necessary. They are to be seen, however, in the accompanying photographs. Along the upper part of the frame at the end and along the sides are placed small brass hooks, into which are slipped the loops of tape sewed on the rubber sheet.

When giving the bath, the bedclothing, excepting a sheet, is removed, and then the rubber sheet over a blanket is placed under the patient. The end pieces of the frame are then placed upright between the mattress and the bedstead and pushed down until they rest firmly on the iron sidepieces. Then the rest of the frame is fitted into place (see Fig. 2) and the rubber sheet is lifted up over the bars and hooked on the outside by means of the loops of tape (see Fig. 3). The rest of the sheet is allowed to hang down over the sides of the bed, thus protecting it from any water that may splash out. In the illustration it will be noticed that the rubber sheet is not quite wide enough to give this protecting flap. By having the end-pieces open, after the bath is over, this part of the sheet may be unhooked, lowered, and the water allowed to run out into a tub.

Such a frame can be modified so as to meet other requirements, *e. g.* with the wide double bed, the lower part of the end-pieces need be made only long enough to rest on the side bars or on the support for the slats in the bed, the tub frame being built so as to stand on one side of the middle of the bed. By this means, baths can be given as easily in private practice as in the hospital, for there is no lifting of the patient, and no danger of soiling the bed; the frame can be put together or taken apart with ease; by undoing the sheet, the water can be drawn off at the side as well as at the foot. A distinct advantage is the cheapness of the affair, for any carpenter can make the frame complete for three dollars or less.

A still simpler form, which was first made, consisted of two end-pieces of board with a square notch cut in the top, into which fitted the ends of the two side bars. This, of course, is not quite so light, nor does it allow the water to be taken from the foot of the bed.

The plan, as is seen, is very simple, capable of being modified to meet the varying circumstances, and yet so efficient in giving to the patient the benefit of the Brandt treatment with a minimum amount of disturbance, that one cannot urge too much its more general adoption, even in private practice. As shown by the hospital records, the drops of temperature and relief of symptoms obtained are fully as good as in the more laborious tubbing.

St. Luke's Hospital

The Treatment of Inoperable Cancer.—Alfred Cooper reaches the following conclusions: (1) In cases of inoperable sarcoma, the patient should have the option of a resort to the use of Coley's fluid. (2) In cases of inoperable cancer of the breast in women of about forty years of age, in whom the menopause has not occurred, the operation of oöphorectomy should be proposed, and this treatment may be combined with thyroid feeding. (3) In cases of inoperable rodent ulcer, and in the superficial malignant ulceration in other parts, the Röntgen rays give a good hope of improvement. (4) In cases in which these other methods are declined, or are inapplicable, the internal administration of celandin is worthy of trial, and when the case appears quite hopeless, morphine should be pushed without hesitation. (5) Parenchymatous injections of acetic acid are also worthy of trial —*Medical Press and Circular.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 30, 1901:

	Cases	Deaths
Measles	427	12
Diphtheria and croup	283	46
Scarlet fever	183	20
Smallpox	16	2
Chickenpox	50	.
Tuberculosis	238	166
Typhoid fever	67	18
Cerebrospinal meningitis	..	3

Lumbar Puncture in Tuberculous Meningitis.—J. K. Friedjung is not inclined to attach too great diagnostic or therapeutic value to this procedure. Headache may sometimes be relieved by it, and possibly life may be prolonged slightly, but this is doubtful. As regards diagnosis, a clear fluid obtained on puncture is an indication of a tuberculous, rather than a purulent, process; but the converse is not true, and cloudy serum may be obtained in cases that are of tuberculous origin. During the stage of irritation, the tubercle bacillus is to be found in smears in 33 per cent., in the stage of pressure in 50 per cent., and in that of paralysis in 75 per cent. of the cases. That is during the earlier periods, when its aid is most needed, the method is least helpful, while at the time when it is likely to give positive results, the clinical picture is usually too clearly cut to require confirmation in this way.—*Wiener klinische Wochenschrift.*

Tuberculous Peritonitis.— B. C. Frazier gives a general description of the disease and reports one case. His patient was a woman of twenty-seven years who presented the general symptoms of acute inflammation in the region of the gall-bladder, calling for exploratory abdominal incision. The latter revealed adhesions (presumably from tuberculous peritonitis) between the inferior border of the liver and the bowel. The adhesions were slight, and no gallstones were found in the bladder. On further investigations, spider-web-like adhesions were found all over the visceral and parietal peritoneum. These were broken down, the wound was closed, and patient put to bed. She recovered rapidly. There was no fever after the third day, but little pain after the second and third day, and the patient was up in two weeks. She has gained flesh, and weighs more now than for several years.—*American Practitioner.*

Musculocutaneous Appendix on the Chin of a Newborn Infant.—Ettore Bidone reports the case of an infant which had a little projection standing out horizontally from the center and lower end of the chin. It was club-shaped, 1.3 centimeters long, ½ cm. in diameter at its largest and 3 mm. at its smallest portion. The author removed it, and found it to be composed of muscular and cutaneous tissues. The author believes the strange growth to have been an amniotic adhesion. Van Duyse holds in regard to preauricular appendices, dermoid tumors, and cutaneous formations on the ball of the eye, that they represent persistent adhesions between the surface of the amnion and that of the embryo. It is possible that this anomalous tumor of the chin may belong to the same class.—*Archivio di Ortopedia.*

Urobilinuria in Chlorosis.—Ernesto Cavaccia concludes from experimentation and clinical observation that in acute chlorosis and at the beginning of relapses there is increased but temporary urobilinuria. In from about four to seven days, the daily amount of urobilin tends to become constant, and is sometimes even below normal. Physical overexertion, cold baths, fever, and hot baths may induce urobilinuria in chlorotic patients.—*Il Policlinico.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 30, 1901:

OPTIMISM VS. PESSIMISM IN THE SURGICAL TREATMENT OF CANCER.

BY ROBERT ABBE, M.D.,
SURGEON TO ST. LUKE'S HOSPITAL.

THE temperament of any medical man, whether physician or surgeon, is to some extent responsible for his taking a hopeful or discouraging view of whatever disease he is brought to face; hence we find men who decry the surgery which pretends to cure cancer by operation, and an occasional case of recurrence is, to such, long remembered in advising others to avoid surgery.

There are certainly many physicians who are loath to send the victim of cancer to the surgeon until it is forced upon them by the peril into which neglect has brought him.

In some instances there may be justification for this dread, by unhappy experience of past hasty endings of some simple case whose end has been shortened.

Even the thoughtful surgeon himself is brought abruptly to a halt by occasional disaster, or by the overwhelming return of disease in patients which he fondly hoped he was greatly benefiting. We all know that the late Dr. Sands refused to operate on mammary cancer from conscientious motives in the year just before his death.

I believe I am right in saying that there is a much brighter aspect to this question to-day than ever before.

The search for a causative germ-origin of cancer has not helped the improved outlook.

There is, perhaps, no more stimulating reason for good work than the growth of opinion among practical men that cancer is almost uniformly a local disease at the start. It cannot be likened to the primary sore of a syphilitic taint, which it is practically useless to cut out, for the cancer lesion *can* be cut out, and the system is free forever in a great number of cases. It may be left long enough where it first starts to beget infarction, and start anew in unnumbered points throughout the body, but not so at first.

Unmistakable evidence proves that when the disease reappears after operation the so-called "recurrence" is not a return of the disease, but a continued growth of left-over particles.

This fundamental fact in the study of the subject should be so indelibly impressed on the mind of the operator that it is present every moment of operation, so that he shall give the widest possible berth to the apparent growth.

The truth of this fact is shown by the localization of the recurring nodules, either in the immediate precincts of the scar, or in the nearest lymphatics.

This is a definite law in cancer growth, and fixes in the mind of the operator the direction of his endeavors.

The only conclusion to be arrived at is that a wide excursion must be made about the disease to include invisible particles in the lymph channels of the skin or beneath it.

But the novice in surgical operations on cancer is appalled by the gap of tissues left when he does what he knows he really should do; hence he curtails his cut, a little here and there, and tries to get his wound "nicely closed," which balm he applies to his soul when he joins the friends in congratulations that it is "all out."

The recurrence is always in the skin near the scar in such cases.

I speak of the immature operator in this field, because one finds to-day an increasing contingent of men willing and anxious to operate because the risks are so far simplified, and primary union so much more easily attained by modern surgical methods.

It cannot be too emphatically brought to the front, that if one will do surgical work, he must be guided by thorough understanding and willingness to do the best, or not attempt it, in this field especially.

No greater help has come to hand in aiding this wide cutting than the use of Thiersch skin grafting. I would even put it first among the valued adjuncts of cancer surgery. Halsted, more than any one else, has emphasized the elaborate use of this, and he removes almost all of the mammary area, applying the largest cuttings of grafts that can be taken from the patient's thigh. It is along this line that considerable of his best work has been carried on.

Encouragement has grown as operations have been elaborated, so that the time consumed in completing a proper excision is now at least double that formerly required. Hence all the best resources of surgery have to be brought to bear to sustain the patient in what has become an ordeal for both patient and surgeon. Nevertheless, it is through this increasing burden of work and responsibility that the operation has been raised from the opprobrium which it had justly received.

My own feeling is growing stronger each year that what may be honestly called a skilful operation to extirpate a cancer in any part of the body requires all the coolness and courage that a man can bring to bear on the hour or two of concentrated work.

It is out of the growth of the elaborated surgical methods that a more optimistic view has come into existence.

One must have seen the sequel of neglected and unoperated cases of cancer, common as they were in comparison twenty-five years ago, to note the contrast, and feel that a beginning has been made in conquering this frightful disease.

We occasionally see such sickening cases to-day in those who have been the victims of faith curists. I have seen three such in sorry plight two of them beyond hope when surgery was called to aid.

My own observation compels me to affirm that a radical cure can occasionally be hoped for in a few cases of cancer by extirpation, and that the resources of surgery have so far mitigated the suffering from malignant disease and prolonged life that we may look upon the present control of the

protean forms of the disease as making a long stride toward its mastery.

Every surgeon must look back upon a gratifying list of cures, and it bears on the positive statement I have made to be able to speak of a few which will emphasize the value of operative work.

Cancer of the Breast.—Until recent years, mammary cancer afforded the least hopeful field for the surgical eradication of the disease of any part of the body, excepting, perhaps, cancer of the alimentary canal.

It still would be a question in the mind of the conscientious operator whether the frequent recurrences which take place in the practice of every surgeon justify him in continuing to subject the patient to the mutilating operation, were it not that many, if not most, of the victims of this dreaded disease are granted a long respite and often many years of immunity after he has done what he can.

At a recent meeting of this society, Dr. Bull showed a lady with non-recurrence twelve years after he had excised a malignant breast.

It is difficult to find in my private notes any case which has had so long a freedom, but out of more than one hundred and fifty excisions for cancer, excluding all benign growths, which I have recently looked into from my own hospital and private cases, I have not been able to get response from more than half of the latter, so scattered do patients become. Of these I found 50 per cent. survived the three-year limit. One case survived six years; one five and a half; four, four years, and so on. Yet it is not in the question of percentage entirely that one finds satisfaction, but rather in the gratification that certain unequivocal cases give where disaster threatens.

Two such cases which I have recently seen may illustrate: One, a young lady—the other, a lady over seventy years. Five years have gone by in each case. In the young woman, malignant disease had spread to the axilla. It has never returned. The elder patient would have come to-night, had I desired it, to show her perfect health, but said she had no objection to my mentioning an incident of some interest. She is the widow of Dr. Morton, the discoverer of anæsthesia, and postponed operation a few days in order to be present at the semi-centennial in Boston of the first administration of ether. Then she returned to New York and took ether herself for the first time, at seventy-two years of age. A malignant tumor occupied the outer quadrant of the breast, and the axillary glands were involved. The skin was adherent. Her health and faculties are still perfect, and there is no trace of trouble.

Sarcoma of the Tongue. J. P., a youth of seventeen years, with a growing tumor of the left half of the tongue, projecting above the dorsum, but mostly buried in the muscle. Removed under cocaine August, 1885. Sixteen years later there was no return. The tumor had a recognizable fibrous capsule, and was examined by Drs. Hartley, Ferguson, and G. T. Elliot, who pronounced it angiosarcoma.

Epithelioma of Tongue. Mrs. F., aged thirty-three years. Four months since a small, hard pimple on right side of tongue, toward the back part, developed into a painful indurated ulcer, involving the edge and dorsal aspect of the tongue, apparently caused by a rough tooth. I excised ulcer and neighboring part of tongue August, 1897. Two months later, a chain of rapidly growing lymphatics appeared beneath the jaw, along the sternomastoid muscle. The original tumor was reported by the pathologist epithelioma, and the several glands, which were most perfectly removed, were also malignant. The patient remains absolutely free from suspicion of return more than four years from operation.

B. F. W., aged sixty years. In July, 1898, a small indurated cancer existed on the back of the left edge of the tongue. I excised the growth freely, with sound muscular portion of the tongue near by, to insure wide margin. Cocaine anæsthesia was used. The microscopical examination by Dr. F. C. Wood showed epithelioma. There was no return after three years.

Mr. V., in September, 1897, I removed a typical carcinoma from beneath the tongue, a dense mass which a nickel would about cover. It was already attached to the gum behind the incisor teeth, and encroached on the tongue.

Free incision was made below the chin, and thorough excision of the diseased part, with additional precaution of chiselling off the posterior wall of the jaw nearby. Dr. Hodenpyl reports the tumor epithelioma of the papillomatous variety. At present writing, four years after, the patient is entirely free from suspicion of return.

Epithelioma of Face.—Dr. M., China. After three removals of a true epithelial cancer of the cheek, near the nose and lip, a recurrence took place, which, when presented to my notice, was about the size of a nickel. The first operations had been done by skilful surgeons in Peking, and they now felt that some extensive plastic operation must be performed. I excised the growth with a good margin of healthy skin, and covered the defect by sliding the lip toward the middle and lowering the nostril.

A small, hard lymphatic was also removed from below the jaw. Seven years have passed in perfect health and no recurrence.

Epithelioma of Floor of Mouth.—Mrs. B., aged forty-five years, for a year noticed a small lump beneath tongue, adherent to the gum, which I removed in the spring of 1897. A subsequent return on the periosteum adjacent and the development of three submaxillary glands required a secondary operation, in which I chiselled away the inner bony wall of the jaw and removed the glands. This I have usually found to be perfectly competent to eradicate the disease, without excising the thickness of the jaw. After four years the patient remains well, except for one small gland in the neck, which I deemed best to leave.

Epithelial Cancer of the Palate.—One year ago the Bishop of M., over seventy years of age, was referred to me for an ugly thick epithelioma of the right half of the soft palate, which fortunately had not extended quite to the wall of the pharynx, but crossed a little over to the left of the middle line anteriorly; it came to the junction of the hard and soft palate. By injecting cocaine along the palatine nerve and a little outside the line of tumor, I was able to remove the growth under cocaine anæsthesia. I entirely circumscribed the growth with galvano-cautery knife, and made a much more perfect excision than I had thought possible. The wound healed quickly, and has remained an absolutely perfect scar, restoring the voice to the full use. The tumor was reported to be a typically epitheliomatous cancer, with no invasion in margin of incision.

Resection of Upper Jaw for Sarcoma of Maxilla.—A gentleman from Virginia, sixty-three years of age, presented himself, March, 1896, with a most un-

promising-looking tumor of the upper jaw and roof of the mouth.

It presented a soft tumor of the front of the face, raising the wing of the nose, filling the nostril, bulging in the roof of the mouth, and including the gum, and extending well over on the opposite side of the roof. Examination showed it to be a soft mixed-celled sarcoma. After doing tracheotomy and tying both external carotid arteries, I resected the entire right upper jaw and the roof of the mouth over part of the left, with the left lower turbinated bone and the bony septum, which was also invaded. It seemed at the operation that I had been able to get well beyond any apparent disease, and I was well satisfied that an apparently hopeless case now offered hope of improvement.

I may add, that some enlarged lymphatics near the carotid were removed for security. Five and a half years have gone by, and the patient has shown not a single trace of disease. He maintains perfect health, and by a good plate, worn with ease, gives little evidence of operation, either in speech, eating or appearance.

Resection of the Jaw for Epithelioma.—In the spring of 1895, six and a half years ago, a lady came from the South with a large protruding, spongy epithelioma of the alveolar and front part of the right upper jaw, pushing the lip forward and encroaching on the roof of the mouth well back to the middle. I resected the right upper jaw and part of the left, getting well beyond the apparent disease. The patient remains in perfect health to-day, and without recurrence.

Sarcoma of Abdominal Wall.—Mrs. P.—A large, projecting dark-purple mass, as large as nearly half a cocoanut, projected from the abdominal wall above left hip, and had been concealed from her physician during its growth of a year or more, while she resorted to Christian Science treatment, as she was an ardent faith curist. The tumor finally ulcerated and became inflamed and painful, and her old physician immediately sent her to me. I excised the mass widely and left the wound to granulate and cicatrize. Two and a half years have passed, and the scar and patient present the appearance of perfect health.

Sarcoma of Abdominal Wall.—Mr. F., a farmer, worked as long as he could endure with a large projecting purple tuberous tumor of the abdominal wall in the epigastrium. It originated in the skin, but had involved the deeper layers and the muscular aponeurosis when I removed it in 1892. The photographs show the tumor with extensive area of removal, and the fine scar resulting from generous Thiersch skin grafts. The patient was alive and well, and working eight years after, with a healthy scar.

I have sufficiently illustrated the life-long immunity which operative work often insures, and believe that one cannot seriously think of the subject of malignant disease, and the results already attained, without recognizing the brightening outlook, and feeling the same exhilarating sentiment of hope which inspires the patient who to-day has been relieved of his burden of disease.

Removal of Large Sarcoma of Kidney; Patient Well Ten Years Later.—A renal sarcoma, weighing seven and a half pounds, was removed by Dr. Abbe from a child whose weight was fifteen pounds after operation. The child recovered, and has grown in perfect health, and remained without sign of disease ten years later. (See report of meeting of Practitioners' Society, November 1, 1901.)

AN EPITOME OF THE SUBJECT OF RHEUMATISM AS CAUSE AND EFFECT IN INFLAMMATION OF THE THROAT*

BY WILLIAM CHEATHAM, M.D.
LOUISVILLE, KY.

RHEUMATISM has been recognized for years as a cause of throat inflammation, even as far back as 1710; so the subject I present for your consideration to-day is not a new one, yet one, I think, of much interest. No part of the throat seems to escape in this affection known as rheumatism. I think we have yet much to learn of its many manifestations and its etiology.

Acute rheumatism is, no doubt, an acute infectious disease. F. Mayer seems to have found the specific cause; he has obtained from the tonsillar mucus cultures of a type of streptococcus, which if injected into animals produces a local infiltration and necrosis, but no suppuration, and after a lapse of six or ten days, inflammation of the various joints, with a serous or sero-purulent exudate, with pericarditis, pleurisy, endocarditis, etc.

R. Oppenheim and Lippman, in ten cases of acute articular rheumatism, found in six a peculiarly shaped diplococcus. Melkich reports in the blood of twenty-one of twenty-five cases of acute rheumatism that he found the bacillus described by Achalme. I think this germ of rheumatism vents itself more often upon the lymphatics of the throat; the tonsils suffer more frequently, if follicular tonsillitis is rheumatic, than other parts of the throat; whether cause or effect, one may question. Surely there is a uric-acid diathesis back of most cases of relapsing or recurring tonsillitis; in some cases there is an autoinfection from the intestinal tract.

Gerhardt has properly termed the tonsil "a physiological wound."

Tonsil tissue is found in the fauces, pharynx, nose, base of tongue, larynx, and many other parts of the body; but it is the faucial tonsils to which I particularly refer. The tonsils are said to create young leucocytes and excrete old ones. This is more active in childhood.

Fowler has published twenty cases of acute rheumatism ushered in by acute tonsillitis. Lennox Brown says the rheumatic diathesis is always present in these cases of relapsing acute tonsillitis. Wagner finds the same germ in rheumatic affections, in the tonsil, joints, and other parts of the body, and holds that the angina is the first manifestation in most of the cases. Graedel says the tonsil is the local point of infection, from which the cocci or germs invade the other parts of the body.

In a recent article by St. Clair Thompson on "Rheumatic Fever in Throat Affections" occurs the following: "In his Milroy Lectures, Newsholme expresses his views that it is probable in rheumatic fever the specific germ enters the system at the tonsils, or some other part of the nasopharynx."

The view that tonsillitis is often of rheumatic origin, and is the initial manifestation of acute rheumatism, if not the actual primary lesion, is indorsed by some observations of Bertram Abrahams. His conclusions are as follows: "(1) The more common varieties of rheumatic sore throat fall into two main categories—faucial erythema, and tonsillitis proper. (2) Faucial erythema is more common in adults; rheumatic tonsillitis in children, in whom it usually assumes the follicular type, quinsy being more common in older subjects. (3) Faucial erythema is an initial manifestation of acute rheumatism; tonsillitis may be the actual

*Read before the Louisville Clinical Society.

initial primary lesion. (4) Many cases are now definitely on record in which endocarditis has followed a non-scarlatinal tonsillitis unaccompanied by joint pains. In numerous other instances, the tonsillitis has immediately preceded an attack of arthritis or of chorea. (5) The presence of the same microorganisms in the tonsils, joints, blood, and urine is evidence in favor of the participation of pyogenic cocci in the etiology of rheumatism. The most common organisms were streptococci; more rarely staphylococci, and the Fraenkel-Weichselbaum diplococcus." From these views it is evident that the author regards the tonsils as the most probable port of entry of the rheumatic virus.

In a very full paper, in 1894, on the relation of sore throat and acute rheumatism, Buss came to the conclusion that the throat is in many cases the site of the entrance of the rheumatic infection. The observations of Poynton and Paine carry these conclusions considerably further.

A question here presents itself as to whether the rheumatic symptoms, the heart and joint involvement, might not depend upon the invasion by other germs through the tonsils at the same time, and upon the action of their toxins. Shurley, Kyle, Bosworth, and all the recent authors upon diseases of the throat give rheumatism as one of the primary and common causes of tonsillitis, pharyngitis, and perichondritis of the larynx. They speak of one of the principal points of differentiation, the examination of the urine and blood, but especially of the urine. Frequently, after cauterizing the nose, I have seen to follow acute tonsillitis, fever with rheumatic symptoms, which are controlled by such medication as used in acute rheumatism. I do not believe that the salicylates will abbreviate the local appearances of a well-established case of acute follicular tonsillitis, but they will control the pain and fever. In my own case, I can eat sweets for a few days, get up an indigestion, an acute tonsillitis, and pain in head, limbs, and back; in this case, the invasion is not, I think, from without, but the germ may have been dormant in the tonsil.

There is a form of rheumatic sore throat, pure, in which the pain is far more pronounced than any other local manifestation of the disease; the pharynx is slightly hyperæmic, rather purple in color, and the pain is very great. There are many recurrences, the pain comes suddenly, is peculiar in character, and changes position often.

Kronenberg reports a case in which acute follicular tonsillitis and acute rheumatism followed the removal of hyperplasias from an inferior turbinal. Some time later the other side of the nose was operated upon. One week after this second operation the patient developed rheumatism of the knees, ankles, elbow, and shoulder, pericardial friction, pleurisy, and consolidation of the lung, and death followed.

Packard thinks the tonsils act as barriers to such infections. He says during or after tonsillitis, complications with typical acute articular rheumatism may appear. He considers rheumatism an infectious disease, dependent upon a variety of bacteria, and the phenomena of the disease to be due to toxin absorption. He says it is probable that the toxin causing rheumatism may be produced by an attenuated microorganism, and the frequent entrance of the microorganism by the throat may explain the occurrence of acute articular rheumatism instead of ordinary septicæmia or pyæmia.

St. Clair Thomson comes to the following conclusions: "The foregoing pages indicate that there is a general acceptation of the view that an undoubted association exists between rheumatism and tonsillitis. This is expressed from two points of view; one is that the rheumatic poison enters the system through the tonsil, the inflammation of which is the first local expression of the disease; the other view is that tonsillitis is, in certain cases, one of the rheumatic manifestations of the rheumatic diathesis. These views are supported by numerous observations, of which I do not pretend to have given more than a selection. Many of the clinical records are too fragmentary to advance the subject, and it seems to me that the various theories which have been propounded are somewhat premature, and that it is much safer to await further pathological investigation to show which of our clinical deductions is trustworthy. Further knowledge is required as to the nature of rheumatism itself, and also as to the various causes and forms of tonsillitis associated with it. So far peritonsillar abscess, or quinsy, is one form which is not accepted as commonly of a rheumatic nature. It is not mentioned by Fowler or Mantle, and Hingston Fox includes it as a rheumatic disease. Trousseau does not particularly refer to tonsillitis as a forerunner of rheumatic fever, but to an evanescent form of sore throat. Evidently the subject will bear closer investigation. The present state of our knowledge on the relation of tonsillar affections to rheumatism might be summarized as follows: (1) It is undoubted that a certain number of cases of acute rheumatism are preceded by an angina in a proportion varying from 30 to 80 per cent. (2) Both rheumatism and angina have many etiological points in common—season of year, cold, wet, fatigue, depression, vitiated air, etc. (3) The connection of angina and rheumatism, though undoubted in a number of cases, is not yet clearly established. (4) The tonsil may be the port of entry of the rheumatic virus, although the naked-eye appearance of the throat gives no indication of its being affected. (5) The particular affection of the throat which is associated with rheumatism is not yet established. Apparently it is not peritonsillar abscess (quinsy). (6) Peritonsillar inflammation does not appear to be arrested by the administration of anti-rheumatic remedies. Many cases of parenchymatous and lacunar tonsillitis, on the contrary, are considerably benefited by the administration of salicine or salicylate of sodium. That this action proves the rheumatic nature of the disease cannot yet be accepted. (7) The question requires further research in two directions: One in differentiating the various forms of angina, and settling the one which is associated with rheumatism; the other in further research to discover the true nature of rheumatism."

My experience in my own throat, as stated before, is, first, an exposure to cold or an indigestion from eating sweets, usually an inflamed, painful throat, fever, followed by pain in back, limbs, and joints, with the development of an acute follicular tonsillitis. Only last week a lady came to see me complaining of a painful sore throat; she had fever; no pain in any other part of the body; both tonsils were quite red; I gave her a calomel and sodium-bicarbonate purge. The next day she had a well-developed case of follicular tonsillitis, with high fever and great pain in back and limbs and joints. I gave her a hydrogen-dioxide and bichloride-of-mercury gargle, with phenacetin, salicylate of sodium, and strychnine sulphate to take internally. This controlled the pain, but the local symptoms ran the usual three to five days' course, although the treatment was begun so early in the invasion.

To return, then, to the title of the paper. My belief is that chronic rheumatism causes frequent attacks of inflammation of the tonsils, pharynx, and larynx;

that acute exacerbations in chronic rheumatism and acute rheumatism are frequently ushered in or preceded by an acute tonsillitis; that following these attacks, we may have all the heart, joint, and other lesions that we find in any rheumatic affection.

It is true, as said before, that these lesions may not be rheumatic, but depend upon other toxins. As yet we are not able to distinguish them.

In Kronenberg's case the operations were a month apart. The salicylates controlled the swelling of the joints, the fever, and the pain; but there was a relapse shortly, with the heart and lung complications, and death. I cannot believe that the infection in this case, or in any case following surgery of the nose, and that seen in cases following exposure to cold or indigestion, such as my own case, depend upon the same germ. It is true, the same germ in all the cases may be lying there dormant, and develop only when the proper soil is present, which occurs when the system undergoes some shock, or the unclean secretion from the nose passes over the tonsil. But surgery in other places than the nose is not followed by such an affection, nor usually by such affections of the joints, heart, pleura, etc.

G. B. Hope says: "The theory is not correct, as the salicylates do not control the symptoms; because, as people get old, rheumatic and gouty tonsillitis gets less rare; because his bacteriological investigations do not prove it; because recurring attacks of tonsillitis are rare in cases presenting unmistakable evidence of a rheumatic attack; because cases of acute tonsillitis have developed when the patients were thoroughly saturated with the salicylates."

In answer to these objections, we might say that in the old the tonsils have atrophied. No one says acute tonsillitis is present in all attacks of acute rheumatism. The lesion in the tonsil may be but slight, even so slight as not to be seen.

Poynton and Paine in the *Lancet* of September 22 and 29, 1900, report such cases, and cases in which, when there were slight acute exacerbations in the tonsillitis, there was an acute attack of rheumatism. It is a well-known fact that a patient may be thoroughly saturated with quinine, yet have a malarial chill, and that mercury and potassium do not always cure syphilis, and that syphilis is the most common cause of iritis. When a syphilitic iritis is cured, the syphilis may not be cured, and may even afterward run a very active course, yet it is rare to have a return of the iritis. Rheumatic iritis is, however, different, as relapses in that are quite common. Why may we not see tonsillitis, then, even when the patient is saturated with the salicylates, or no tonsillitis, even with acute or subacute rheumatism present?

Local Ventilation.—The generally received doctrine of placing inlets for natural ventilation about four or five feet high, with openings toward the ceiling, and outlets near the ceiling or at the ceiling, is in the main correct; but where there is excessive floor pollution, as in the daywards of idiot asylums, if mechanical ventilation is employed, and warmed air driven in, then it is certainly best to make large openings on a level with the floor, and so sweep away offensive odors. Even with natural ventilation it is certainly useful in such cases to have openings on a level with the floor, closed at will, so as to allow fresh air to stream freely over the surface.

The great principle in ventilation is to remove polluted air as quickly as practicable, and that is best done by having the exit openings as close as possible to the localities where the air is polluted. Such a position chosen systematically is not possible with natural ventilation; it is only possible with mechanical ventilation.—A. Wynter Blyth in *Public Health*.

RHEUMATIC AFFECTIONS, THEIR PATHOGENESIS AND TREATMENT.*

By MARTIN A. H. THELBERG, M.D.
NEW YORK.

THOUGH we all know the differences in the pathology, clinical course and symptoms of typical rheumatic fever, subacute and chronic rheumatism, and rheumatoid arthritis, and though we all have learned that under no circumstances must we class the latter under the heading of rheumatic affections, still recent investigations of as able men as Garrod of London, Wasserman, and others seem to justify us in classing not only many cases of rheumatoid arthritis, but also chorea and tonsillitis, under this heading. Clinical experience seems also to prove the close relationship in at least many instances.

Garrod, in his splendid article in the *Lancet* of March 16, 1901, after describing various varieties of rheumatoid arthritis, concludes that the organic changes usually described as characteristic of this disease are "not the products of a single, definite morbid process, but are merely lesions which are apt to occur in joints that have become the seats of chronic disease of various kinds."

Delafield and Prudden, in the sixth edition (1901) of their "Pathological Anatomy and Histology," say, under "Arthritis Deformans": "This name has been applied to a variety of chronic inflammations of joints. It may be idiopathic, or due to rheumatism, or to injuries, or follow an acute arthritis."

We may, however, agree with Garrod, that in the great majority of instances rheumatoid arthritis in any of its varieties appears as a primary disease, presenting from the onset its characteristic features, without the patient previously having suffered from any trouble suggestive of a truly rheumatic origin.

Regarding the relationship of chorea to rheumatism, Wasserman, Westphal, and Malakoff have succeeded in getting a pure culture of a diplococcus of certain morphological and other characteristics obtained from the meninges of a fatal case of chorea. On injecting this culture into a series of eighty rabbits, fever, multiple arthritis, and all symptoms and lesions characteristic of rheumatism were observed. (See *Berliner klinische Wochenschrift*, 1899, No. 29.)

Poynton and Paine again have, with the pure culture of a diplococcus obtained from the rheumatic nodules of the knee of a patient with rheumatic fever, succeeded not only in producing all the symptoms and pathological lesions of acute rheumatism, including arthritis, effusion, and valvulitis in rabbits inoculated with this diplococcus, but they observed also in one instance sudden, choreiform twitchings of the face and limbs of one of the rabbits. Upon necropsy the identical micrococci were demonstrated in the pia mater and endothelial cells of the capillaries, dipping into the motor cortex from the surface. This rabbit also had polyarthritis and valvulitis.

Dana succeeded, several years ago, in demonstrating a diplococcus in the meninges of a fatal case of chorea (*American Journal Medical Sciences*, 1894), as later have Wasserman and others, who coincide in the view that this diplococcus is the specific cause of rheumatism and chorea.

Whether gout stands in as close relationship to rheumatism is not demonstrated, though Mordhorst, in a recent article (*Centralblatt für innere Medicin*, Vol. XIX, p. 409), claims intimate associations between the two, in which he is well supported by the French.

That rheumatic fever itself is a bacterial disease has of late years gained more and more adherents,

*Read before the Society of the Alumni of the City Hospital, New York City, November 13, 1901.

and various microorganisms, especially diplococci, staphylococci, and bacilli, have been found by a horde of observers in the nodules, synovial membranes, fibrinous and serous exudates, blood, urine etc., of persons suffering from acute rheumatism.

The researches of Poynton and Paine (*Lancet*, September 22 and 29, 1900; May 4, 1901, and *British Medical Journal*, September 21, 1901) are the most painstaking and conclusive on this subject. They found a diplococcus of constant and peculiar morphology in sixteen consecutive cases of rheumatic fever, and obtained pure cultures therefrom by anaerobic incubation of the rheumatic nodules, pericardial, and synovial fluid, and valvular vegetations in a medium of milk and bouillon, rendered slightly acid by lactic acid.

The intravenous injection of this culture in rabbits produced stiffness of various joints with swelling, definite systolic murmur, and other rheumatic manifestations. Post-mortem examinations showed arthritis with effusion, mitral and tricuspid valvulitis, etc. From this effusion, or the valvular vegetations, a pure culture of the diplococcus was again obtained, completing the chain. Wasserman, Malakoff, Fitz Meyer, and others have obtained similar results.

Achalme, Thiroloix, and others have again found a peculiar bacillus, which they believe the infective cause of rheumatism, while Sahli, Singer, and others have obtained a staphylococcus from the exudates, etc., of rheumatic patients. Triboulet found a bacillus resembling that of Achalme, but he found also a diplococcus in several instances, and in two cases the Achalme bacillus and this diplococcus were found together. The argument of Triboulet is, therefore, that the diplococcus is the cause of simple rheumatism, while severe and complicated cases are due to this diplococcus and + the Achalme bacillus.

It may be safe to predict that many cases of apparently typical rheumatism will, without doubt, on closer study prove to be pyæmias, or infections with microorganisms, differing from those of true rheumatism, as pus-cocci, gonococci, etc., while again many cases of chorea, tonsillitis, and even of rheumatoid arthritis will prove true rheumatic affections.

Poynton and Paine, in a recent article in the *British Medical Journal*, September 21, 1901, admit, however, that "the diathesis is such an important fact that it is probable that there is some peculiarity in the tissue changes of rheumatic fever which is specific." They add, "In the history of rheumatic fever, heredity takes such a prominent part, and the rheumatic constitution is so clearly recognized that it is hard to escape from the conviction that the disease is not to be explained by the presence and nature of the microorganism only, but that in addition there must be some condition of the human tissue, which is also of importance."

The adherents of the metabolic theories as to the cause of rheumatism have, in the undoubted increase of lactic acid in the blood, seemingly good grounds for their claims of perverted metabolism or faulty assimilation. On account of the increase in lactic acid, the blood in rheumatics is, without doubt, decreased in alkalinity at the same time that the fibrin is greatly increased. (Cabot, "Clinical Examination of the Blood," and Ewing, "Clinical Pathology of the Blood," 1901). The physiologico-chemical theory, that the decrease in alkalinity of the blood is caused by the checked elimination of the sarcolactic acid (which is formed, together with potassium phosphate, during muscular exertion, when simultaneously CO_2 is liberated) by the action of cold on the surface, is again hardly valid, as many cases of rheumatism are seen where neither muscular exertion nor exposure to cold can possibly be ascribed as causative factors.

The nervous theory of J. K. Mitchell and others is, *per se*, equally defective. It seems, however, to me that, in the light of recent researches and scientific deductions, all these theories, *i. e.* bacterial, metabolic, and nervous, will blend most harmoniously into one complete theory, which will have every logical reason in its favor, and at the same time have the unsatisfactory gaps, so to speak, filled.

To this end we will first recall that modern research seems to prove that "immunity" is due to an antitoxic substance in the blood, soluble only in an alkaline medium. As in rheumatism there is an excess of lactic or sarcolactic acid in the blood, whereby its alkalinity is greatly reduced, we have all reason to argue that the immunity to specific bacterial invasion is thereby also considerably diminished, if not nullified. This ought to be especially true of an organism which, as the diplococcus of Poynton and Paine, is found to grow best in a medium made slightly acid by lactic acid. We see a similar instance to this in the infection with the ever-present, though seldom active, pneumococcus of Fraenkel, whenever, from some cause or other, the body resistance or immunity is reduced to its invasion.

If we, therefore, instead of giving exposure to cold (as Prout and others) or muscular hyperoxidation (as Latham) as the cause for the increased percentage of lactic acid and the reduced alkalinity of the blood, consider that these abnormal conditions are the results simply of faulty digestion, assimilation, and elimination, whereby the natural immunity is greatly reduced, and whereby, furthermore, the nerve-centers are made far more susceptible to irritation, we have all the three principal theories on rheumatism combined into one simple and thoroughly scientific theory that certainly has much in its favor.

That digestive disturbances of some sort are the rule in persons suffering from rheumatism, every one will recall from experience. The textbooks on gastro-intestinal disorders have not much to say on the subject, but that is not to be wondered at, as certainly acute rheumatics seldom come under the care of the specialist in that line. It may, however, be of interest to quote some few writers.

W. Ewart (*Lancet*, March 17, 1900) considers rheumatism, in part, a dietetic disease, and that in the wide range of cases the "feeding" plan needs to be represented as well as the "starving" plan. He says also that though meat and beef tea have generally been banished from the dietary, as the supposed source of the excessive lactic acid, still the inability of some patients to manage milk diet makes it a question whether or not this food in their cases might keep up the rheumatic tendency, and become the supply of the increased amount of lactic acid. This view certainly seems reasonable, as milk may cause auto-intoxication, as well as most nutriments.

Ewald says in his "Diseases of the Stomach": "Although I have not met a single case of true gout with coincident gastric disturbances, yet I have seen numerous such examples in chronic articular rheumatism."

Einhorn in "Diseases of the Stomach," p. 470, says: "In a case of arthritis deformans, and in two patients with severe gout, I found achylia gastrica. In several instances, in which only slight symptoms of gout existed, I frequently found hyperchlorhydria."

Murdoch (*Medical News*, August 3, 1901) reports his series of analyses of the stomach contents in six consecutive cases of chronic rheumatism and arthritis deformans, in all of which he found abnormalities, either hyperchlorhydria or achylia. His cases, though all of a chronic nature, were cured, or at least greatly improved, by treatment directed exclu-

sively toward correcting the digestive troubles; wherefore his conclusions are that in these affections, treatment should be employed to suit the existing state of the gastric secretions.

I coincide most enthusiastically in this view, as, after relieving the pain in acute rheumatism, my own efforts in the treatment of this disease have been almost solely applied in the same direction, from which, in every instance, the most satisfactory results have followed. That such should be the case seems to me but natural, when we consider that proper quality and amount of food consumed, proper digestion, and assimilation have much to do with improvement in natural immunity and prevention of auto-intoxication. Every one familiar with the modern treatment of early pulmonary tuberculosis tries his utmost to supply such patients with a greater amount of easily digested food than is necessary for the wear and tear of the body. This is, as we all know, for no other reason than to increase the immunity, as well as the phagocytic action, of the leucocytes. The generally accepted view seems to be that the chief source of the antitoxic substance which gives the blood serum natural immunizing power is the leucocyte. These same leucocytes have, furthermore, phagocytic powers, whereby the organism is, to some extent, protected against bacterial invasion. The great majority of pathologists seem also to coincide with Hofmeister that the leucocytes again are of prime concern in the absorption and assimilation of nitrogenous matter.

If we therefore accept the definition, which seems a probably correct one, that "rheumatism is a general disease of bacterial origin, characterized by especially arthritic and cardiac manifestations," we may also be allowed to add: "Contracted by persons whose blood, on account of perverted metabolism, is of especially low alkalinity and immunizing power." One could even add that in such persons the nervous equilibrium is disturbed by the toxic and irritant products of retrogressive metamorphosis, or disassimilation.

At the semi-annual meeting of the New York State Medical Society, on October 16, 1901, Dr. W. H. Thomson read an excellent paper on "The Pathology and Treatment of Migraine." In this, Dr. Thomson gave as his conviction and working hypothesis that, instead of looking upon migraine as a nervous disease, we will in all instances prevent recurrences by directing our treatment to the correction of the portal circulation and digestion, and by preventing gastro-intestinal auto-intoxication.

In response to Dr. Abraham Jacobi's reminder regarding the heredity of migraine, Dr. Thomson emphasized that the digestive trouble and not the symptom migraine is inherited, in proof of which he claimed that proper prophylaxis directed in that line will, in every instance, positively prevent migraine. Dr. Thomson's views meet so thoroughly with my own very modest experiences that I am furthermore led to propound the query, whether it might not be possible that in rheumatism, as in migraine, the digestive disturbances are inherited, thereby causing the s. c. rheumatic tendency or diathesis.

Regarding the treatment of rheumatism, it may be well to recall that Flint, Gull, Sutton, and others, who long ago closely studied the course and duration of rheumatism under various treatments, found that the disease was not prolonged, and its serious manifestations were not increased, when no treatment whatsoever, except some "placebo," was given. Though since that time the salicylates have gained very great renown for the relief of rheumatic pains, and were at first hailed as specifics in this disease, still they do *not* prevent cardiac and other serious lesions, nor influence the duration of the attack, but are, on the contrary, rather cause for relapses and chronicity, as is so ably and conclusively proven by R. P. Howard.

The treatment has, in all my cases, been directed almost exclusively in the line of digestion and general hygiene, as I have found all my rheumatics to be chronic dyspeptics of some sort or other. It may also be well to point out that these patients in my experience can be divided into two distinct classes. The first are spare, nervous men, or especially women, who often suffer from headaches, lack of appetite, distress after eating, and constipation. They are, as a rule, extremely light eaters, but drink instead a great deal of tea or coffee. Whatever food partaken of is low in nutritive value, and carbohydrates, albumens, and fats are not in proper proportions. The food is bolted and imperfectly masticated. Fresh air, sunlight, and exercise is insufficient; hot baths taken in excess, or not at all, cold baths never.

The second type is the ruddy fat woman, or especially man, with flabby, distended abdomen. Habits sedentary, or lazy. Hearty eaters and drinkers, doing either or both out of all reason, wherefore gastro-intestinal catarrh is of long standing, and general condition below normal, notwithstanding the deceptive appearance. To exemplify the kind of treatment that to me has proven of greatest value, it may be well to cite one of each of the above types.

Mrs. H., housewife, aged twenty-eight years. Both parents alive and well. When the father, who now is sixty-three, was about thirty years old, he was taken with repeated attacks of rheumatism, with fever, perspiration, and polyarthritis, which kept him in bed nearly three years, and incapacitated him for work during about seven years. Recovery was, however, complete, and he has worked hard ever since. His daughter, our patient, has had two children, both now living. No miscarriages. Has had measles, but not scarlatina, diphtheria, nor any previous disease. She has never suffered any especial shock, mental anxiety, sorrow, or injury, and has led a reasonably pleasant and comfortable life. Although always very slender, she claims to have been in constant good health. The appetite has, however, been poor, and she has ever since childhood been especially nervous. The only things she has had cause to complain of have been poor appetite, some "indigestion," headaches, and constipation, until in July, 1900, when, while at the seashore and after partaking of a "shore-dinner," she was suddenly seized with pain in one ankle. She went home and to bed, as the pain and fever increased. A physician was called in, and large doses of salicylates were taken. After the acute symptoms had attacked several joints, she improved and was able to attend to her children and household duties, though some stiffness and pain frequently reappeared. On November 19, 1900, the patient had chills, followed by very high fever and excessive perspiration. Different joints were then attacked, one after the other, and the patient has since that time had most every joint of her body affected, incapacitating her from all work, and even from rising from bed, walking, or attending to her own wants. Several physicians had frequently seen the patient and prescribed large amounts of salicylates, iodides, etc. When first called in the case, on September 14, 1901, I found the patient in very bad condition. She was greatly emaciated, pale, and anæmic in high degree. The muscular atrophy was marked; weight not above ninety-five pounds. The skin was dry, tongue pale and somewhat coated; marked tremor. Slight, soft mitral, regurgitant murmur. Pulse weak. Slightly prolonged expiration at left apex, but sputum examination negative.

Temperature somewhat above normal. Hardly any food was partaken of, especially as distress usually followed. Tea, toast, and oatmeal gruel were almost the sole diet. The almost always present articular pains and stiffness and had frequent exacerbations. Several joints were swollen and tender, but no bony deformities were observed, except second joint of third, fourth, and fifth fingers of the left hand. No pigmentation of the skin, no urate deposits of ears, fingers, or toes, but slight crepitation of left knee, right shoulder, and wrist. Left shoulder has been especially involved, but is now fully normal, except for a couple of persistent nodules.

For treatment, small, repeated doses of calomel were administered and followed by saline. Teaspoonful doses each of sodium bicarbonate and sulphate have been taken every morning up to the present time. One pint of hot water and one-tenth grain strychnine sulphate half an hour before each meal. Cold sponge baths taken every morning (and often, also, at night), followed by brisk rubbing down. Light massage an hour daily. Warm bath once a week, followed by cold sponging and rubbing down. Four meals a day, including almost three quarts of milk, salted, or with some vichy. Three to four eggs a day, beaten or soft boiled; raw oysters or clams, broiled steak or chop at least once a day, with baked potato. One piece of dried toast or zwieback, eaten dry, with each meal. Meat jelly, custard, junket, whey, clam broth, clear soup, or beef tea, with raw egg to be taken alternately at meals. Grapes and orange juice *ad libitum*. A digestant was given at the beginning of meals and a tablet of bismuth betanaphthol an hour after meals. The patient was assisted to a comfortable chair in a well-aired room, where she has gradually remained longer each day in direct sunlight, with directions to exercise different joints and to walk a little at a time. When troubled with pain an anodyne was given, but this has not been necessary more than a few times. After two weeks of this general treatment, freshly made Blaud's pills, with arsenic, were given and are still kept up to the limit.

Under this treatment, the patient has improved wonderfully in every way and surprised me by walking the four blocks to my office without bad effects. This was about three weeks after treatment commenced, and she has since been able to attend somewhat to her home duties, gets in and out of bed, walks about and even takes her own bath, etc. She now suffers hardly any pain, though still rather stiff and tender.

Mr. X., retired sea captain, somewhat over sixty years old, of the hearty-living variety. Claims always to have been well, though interrogation brings forth a statement of the usual symptoms of chronic gastro-intestinal catarrh. Was seized with severe pains in the right knee on the night of September 7 last, accompanied by slight chill, hyperpyrexia, and later perspiration. When seeing the patient in the morning, I found him quite unnerved by the night's suffering. There were considerable redness and swelling of the knee, and the least touch or movement caused extreme suffering. Pulse about 120, temperature 103.2°. A hypodermic of morphine and icebag over the precordia were followed by marked relief. Small, repeated doses of calomel, followed by saline hydragog were given. The joint was carefully sponged off with alcoholic solution of menthol, after which ice was applied also to the knee, which relieved the symptoms considerably.

Without going into further detail, it may be well to say that small, repeated doses of calomel, alkali, and saline cathartics in some form, a few hypodermics of morphine, ice to the affected joint, or joints, and, if necessary, to the precordia, cold sponging, followed, if necessary, by some antipyretic, together with dietetic, hygienic, and hydrotherapeutic measures generally, have proven effective and certainly more so than salicylates. I have not found meat diet contraindicated in rheumatism after the temperature has subsided; on the contrary, when pyrexia, with its coincident decrease in gastric secretion, has disappeared, my conviction is that meat, in some easily digested form, or predigested, or in some of its preparations, as somatose, jelly, beef tea, etc., is of special value. I have during pyrexia even fed many of my patients on beef tea with yoke of egg, somatose solution, or egg-albumen water, instead of on the usual milk diet. The principal thing, in my estimation, is to give especial attention to the digestion and absorption of a rational quantity of food of proper components, with an excess of nitrogenous matter. Attention to the elimination can, however, never be too rigid. All hygienic measures are, furthermore, of prime importance; and fresh air, sunlight, cold spongings, followed by brisk rubbing or massage, are of far more importance than medication

205 WEST 125TH STREET.

MUNICIPAL SANATORIA.*

BY ALFRED MEYER, M.D.,
NEW YORK

IN the preface to the report of the First New York State Conference of Charities and Correction I read: "This conference was organized for the purpose of considering questions of practical importance relating to the public and private charitable and correctional work of this State, in the hope that this and similar annual conferences would exert a powerful influence for good in securing intelligent action upon such questions." Therefore, it is surprising that, with such a large scope, not a single paper was devoted to the discussion of the very largest charitable topic in the world: The care of the consumptive poor. In an audience like this it is scarcely necessary to adduce evidence in support of the statement that this is the largest question of that kind. Everybody interested in charitable work knows it; whether he studies the question by sex, color, or nationality, whether by towns, cities, states, or continents; the figures may be kaleidoscopic in arrangement, but they are terribly uniform in their results, always telling the same pathetic story of one-seventh of the population of the globe doomed to die of consumption. Moreover, in every community vast numbers of these have not even had a fighting chance to get well because of their poverty, nor is there sufficient provision to smooth their way to the grave. And so, everywhere, in foreign lands and in our own, the cry is raised: More must be done for this long-suffering and long-neglected class. But there is another reason besides the nature and enormity of this problem, why it should with propriety find a place upon your programme, and that is because your meetings, attended as they are by philanthropists, charity workers, social scientists, public officers, and physicians, permit of a wide and helpful discussion.

What greater stimulus could we have in the prosecution of our work in behalf of these sufferers than the knowledge that there is something to be done for them, that they are not necessarily doomed to a lingering death. The hopelessness of twenty-five or thirty years ago has given way to the hopefulness, not only of arresting the disease in the individual case, but of preventing the disease in others and, perhaps, of exterminating it altogether. Fortunately, this

*Read before the Second New York State Conference of Charities and Correction, November 21, 1901.

hopefulness is not born of a hysterical enthusiasm, for we all believe with President Roosevelt that "If there is one thing more than another which we do not wish in our civic and national life, it is hysteria in any form;" but it is a hopefulness pervading the entire medical profession, born of a faithful study of facts and figures from all over the world. In our own country, "The diminution of pulmonary tuberculosis in Massachusetts is remarkable, the death rate having fallen from forty-two in ten thousand inhabitants in 1853 to twenty-one and eight-tenths per thousand in 1895" (Osler), or to just about one half. I shall not trouble you very much with figures, but I must quote a very interesting calculation made by Professor Fraenkel of Berlin in a recent number of a German medical periodical. Starting with the assumption that there are eight hundred thousand consumptives in the German empire, and allowing for the cures affected annually at the sanatoria and the reduction thereby of foci of infection, he believes that if provision were made for the care of eight thousand advanced cases annually, there would be a reduction of eighty thousand cases in five years, so that in 1906 there would only be seven hundred and twenty thousand consumptives. If, then, in another period of five years there were a reduction of another eighty thousand, this would already represent one-ninth of the total number and not merely one-tenth, so that it would appear possible "slowly but surely to exterminate the disease." I am speaking of this at some length, because even in educated circles the old idea of the incurability of pulmonary tuberculosis is not yet uprooted, a man so in touch with the philanthropic life of the day as Bishop Potter having fallen into this error in a recent public address. Taking it for granted that one of the most powerful incentives for the erection of sanatoria to-day is the fact that a man has a better chance of recovery from consumption than he would have had fifty years ago, we must in this connection remember two things: First, the disease can be recognized earlier than formerly, and second, the rational sanatorium treatment ought to be instituted early. The medical profession is coming more and more to look upon these two propositions as axioms. Just as Behring's diphtheria antitoxin cures only when administered early in the course of this disease, so does the early application of sanatorium treatment hold the key to the result in consumption. In other words, poor patients must be removed promptly from the conditions prevailing in their tenement homes, and some one else must provide the means to do it. Now, for many years private charity has been grappling almost unaided with this problem, and when we analyze the disproportion between the means at command and the end to be attained, we cannot help admiring the devotion of those engaged in the contest. Finally, it began to dawn on the minds of many men, physicians, philanthropists, and public officers, that, to wage this fight on lines and with means commensurate with its enormity, we must needs enlist the help of the State. Under our system of government, with its jealous guarding of the powers and prerogatives of the individual State, not much aid was to be expected from the national government. In view of this limitation, it would appear reasonable that the United States should at least provide suitable sanatoria for its own servants, its soldiers and marines, and a beginning has actually been made by the establishment of the General Hospital for the Treatment of Pulmonary Tuberculosis at Fort Bayard, N. M., where 263 patients, mostly enlisted men of the regular army, were admitted from October, 1899, to December, 1900; and one hospital has been established under the control of the Marine Hospital Service.

The eyes of those interested were then turned to the individual State, as the ideal political unit to which to appeal for financial and moral support in developing the sanatorium idea. Although Massachusetts (I always like to take off my hat to her) is the only State which has such an institution in successful operation, her example has borne rich fruit. The agitation for similar institutions has spread from State to State, partly through the influence of societies specially formed for this purpose, and partly that of already existing charitable organizations, the labors of physicians, of boards of health, and of the educational work of the press.

In some States, like Maine and Rhode Island, commissions have been appointed to investigate and report upon the advisability of sanatoria; in others, like New Jersey, Connecticut, Illinois, Michigan, and Wisconsin, bills have actually been introduced for their establishment, and in New Hampshire a bill to that effect has been passed by the Legislature; while in Pennsylvania the State has appropriated fifty thousand dollars to an incorporated society, known as the "Free Hospital for Poor Consumptives," and for the past eight years has appropriated five thousand dollars annually to the Rush Hospital for Consumptives.

The development of this great movement in our own State is, perhaps, familiar to all of you. You know that after much discussion and several defeats in the Legislature two appropriations of fifty thousand and one hundred and fifty thousand dollars, respectively, were appropriated, and a Board of Trustees was appointed by Governor Roosevelt to proceed with the selection of a site and the erection of suitable buildings. But, alas! after much faithful work by them, a site has not yet been agreed upon, and for the time being the money is lying idle, the good intent of the State is nullified, and a great and good work is blocked.

But even were the State already actively launched upon this life-saving career, it is perfectly clear to every one familiar with the facts that one sanatorium would be entirely inadequate for the demands upon it. In fact, one of the arguments advanced against the entire movement was the danger that the State would be bankrupted by the many millions of dollars required to care for all the incipient consumptive poor within its borders. It was this consideration, and a feeling, especially among rural legislators, that the great population centers would be the main beneficiaries of such institutions, that led to the conclusion that a State sanatorium should merely serve as an example and a stimulus, and that each municipality should decide for itself, as a sort of "local option," the question of additional facilities and outlay. And so, in 1899, the Henry bill was passed, as follows: "Any municipal corporation, having a population according to the last State census of 250,000 or more inhabitants, shall have the power, whenever its board of health shall deem it necessary for the promotion of the health of its inhabitants, to establish, equip, and maintain, outside of its corporate limits, and at such place or places within the State of New York, and not within the corporate limits of any other municipal corporation, as may be determined upon under the provisions of this act, a hospital or hospitals for the regular treatment of the disease known as pulmonary tuberculosis."

In the autumn of 1900, I made a plea before the New York Academy of Medicine for action under this law, showing that in Greater New York alone there were about eight thousand deaths per annum

from consumption, that there were probably twenty-five to thirty thousand cases in various stages of the disease, that in the year 1899 the city had provided about three hundred and sixty-five beds for them in seven public hospitals, and that twenty-six private hospitals accommodated about one thousand cases more, and of these, a very large proportion (about one-third) were advanced cases—namely, 635 deaths out of 1,839 cases in the public hospitals, and 914 deaths out of 3,050 cases in the private hospitals. It was urged that large numbers of these would never have become advanced and fatal cases, had they, while still in the initial stages, been properly cared for in sanatoria.

There appeared to be no opposition to the project of a municipal sanatorium from the physicians, philanthropists, and city officials present at the meeting. It received assurances of support from the Department of Health and of Charities, and later on hearty sympathy from the Comptroller of the City. As a final outcome, a committee of five physicians, of whom I am one, was appointed by the council to co-operate with other bodies to further the erection of a municipal hospital for consumptives, and the following resolutions were adopted, which may well be accepted as a most excellent enunciation of principles for all similar institutions:

First. Resolved, That the Committee appointed by the Academy be instructed to use its influence to have the municipal hospital constructed for cases in the early and presumably curable stage of phthisis.

Second. Resolved, That while the proper designation for such a hospital would be for curable cases, yet in view of the bad effect a refusal to be admitted would produce upon others, the designation be "Hospital for Incipients."

Third. Resolved, That the Committee be instructed to use its influence to have the hospital placed in a locality which would be most productive of good; where there shall be such space that it shall not become an injury and danger to the neighborhood, as would be the case were it placed in a populous locality.

Fourth. Resolved, that the Committee be instructed to use its utmost endeavors to have such examinations for admission made by thoroughly competent physicians possessed of such moral stamina as shall prevent advanced and incurable cases being sent to the hospital for incipient cases.

Fifth. Resolved, that the Committee be instructed to use its influence to have the rules and regulations of this hospital such that it shall not become an unnecessary burden upon the community.

The possibilities, under this last resolution, in the way of economy, are perhaps greater than appear on the surface. I need only refer to the fact that many incipient cases may do a small amount of work, not only without injury to their health, but with actual benefit to it. The work must be regulated in amount and character by the physician in charge, and may be subject to change from day to day. For many, light farm work is the most suitable. This system has been introduced at the Bedford Sanitarium of the Montefiore Home, with which I have the honor to be connected, and the following products were raised, largely by the patients under supervision of a skilled farmer, during the year 1900—the average number of patients per day then being only twenty-five.

About 30 tons of hay, 160 bushels of potatoes, 100 barrels of apples, 70 bushels of onions, 350 bushels of corn, 1,000 heads of cabbage, 25 bushels of beets, 40 bushels of carrots, 100 bushels of turnips, and twenty different kinds of vegetables. Part only of these products being used in the commissary department, the rest was sold.

In the opinion of the writer, the next step in the evolution of this movement, at least in this community, is to have this committee unite with other bodies and organizations having a similar object at heart, and to appear with them before the Board of Estimate and Apportionment with a request for an appropriation of three hundred thousand dollars for this purpose. The time is now ripe for such a step; all that is needed is a union of forces, and with this sum of money an institution could be erected to accommodate three hundred patients. Boston is already ahead of us. Its city government recently appropriated one hundred and fifty thousand dollars for a municipal hospital for consumptives. In Philadelphia, after ten years of fruitless endeavor, the city authorities are now considering the matter of setting aside one of the outlying city farms for the use of a sanatorium, and at the same time of appropriating eighty thousand dollars for the erection of a plant. Cincinnati, as long ago as July, 1897, opened up an institution of this kind in a fifty-three acre park within five miles of the General Hospital. Up to August, 1899, three hundred and thirty patients had been treated there. When will New York rise to the greatness of its opportunity to bring this blessing within the reach of its consumptive poor? But if the attempt fail in New York, there is no doubt that such failure will be largely, though not entirely, attributable to the expense. Under these circumstances, why should not the bill be amended so as to include cities of the second class? The tuberculosis problem is the same in these as in New York and Buffalo, and the financial obstacles may not be so great. This would permit Rochester, Syracuse, Albany, Troy, and Utica to act, and enough public-spirited citizens and officials may be found in one of these cities to push the project to a successful issue. The first city in the State which erects a sanatorium outside of its corporate limits under authority of the legislature will ultimately find so many imitators among her sister cities that her initiative will deserve to rank among the greatest victories in the anti-tuberculosis campaign. Before closing, I wish to put myself upon record (and I trust that it may prove to be the consensus of opinion at this discussion) that no system of municipal care of consumptive poor will be complete which does not also provide for the care of advanced cases within the corporate limits. Not only will such provision diminish the temptation to pronounce these cases incipients, which would mean occupying the place that of right belongs to others, but it would largely eliminate the depressing and injurious effect of frequent deaths in the midst of the incipients. In other words, the two types of cases should be kept strictly separate, or at least as strictly separate as the present status of medical science permits; the incipient and presumably curable cases in a sanatorium outside the corporate limits, and the advanced and presumably incurable cases in an institution within the corporate limits. Here the latter may be permitted to remain with such comforts as medical knowledge and nursing can bring them, with the added joy of the nearness of relatives and friends until death releases them from their misery. In the prosecution of this work may we have, in the language of Huxley, "Just enough fanaticism as a sort of moral coca, to keep up to the mark," and may the disinterested labors and the wide influence of this conference hasten the day when this policy shall meet the approval of the enlightened citizens and public officers of this city, and of the other cities and towns of the Empire State.

5 E. Madison Avenue

TREATMENT OF DELIRIUM TREMENS AND ALCOHOLIC TOXÆMIA.

By T D CROTHERS M D,
HARTFORD, CONN
SUPERINTENDENT WALNUT LODGE HOSPITAL, ETC

Delirium following the use of alcohol is rapidly increasing and becoming more prominent every year. The hallucinations of snakes and demons are seldom noted, but in their place are conceptions of enemies with guns, of falling walls in the building occupied by the victim, and constant apprehension of death by violence. The term delirium tremens (or "D. T.'s." a popular abbreviation) is loosely applied to all forms of delirium following the use of spirits.

In the recent textbooks, the classification of the different forms of alcoholism is made according to the particular mental characteristics predominating in each individual case, as acute, chronic, delusional, persecutory, melancholic, or dementia. Literally, any person who uses spirits to excess, at intervals or continuously, may have periods of delirium with delusions and sensory disturbances of short duration.

While the early treatment of these conditions is practically the same, the prognosis and later treatment will differ widely. It is important to determine the type and form of the mental disturbance, to ascertain whether the delirium appeared abruptly, or was preceded by evidences of mental confusion, as the domination of some unusual idea, made manifest by peculiar speech and conduct.

If the delirium comes on abruptly, the exciting causes are acute, and point to the formation of toxins, a condition of auto-intoxication. If the delirium has been preceded by mental changes, and transient alterations of thought and conduct occur, gradually becoming more constant and fixed, there are indications or organic lesions of the brain.

It is necessary to ascertain whether the delirium follows from a long period of continuous drinking, or a periodical use of spirits, or whether the drink period was preceded by some physical or mental disturbance arising from organic disease, traumatism, or mental strain. Whether it followed acute disease, severe exhaustion, or whether there was mental instability as the result of hereditary influence, preceding this state.

Alcohol in these conditions may be both an exciting and a predisposing cause. The symptoms will vary with the causes. If the delirium is due especially to the use of spirits, there will be more hallucinations and motor disturbances, the various changes taking place with different degrees of intensity. If the onset of the delirium follows some form of traumatism in persons who are accustomed to the use of spirits, the delusions will be more prominent and refer to some tangible object, or to the actual relations of life.

Should the delirium follow prolonged excess in the periodic drinker, where the alcohol is abandoned before the delirium comes on, intense hallucinations of short duration, prolonged delusions concentrated upon one subject, will follow.

These latter patients are often sent to insane asylums, where they remain for weeks and months.

The general pathology of these cases is a vasomotor paralysis, particularly of the blood vessels of the brain; the dilator and constrictor nerves in the walls of the arteries are affected, and a subsequent congestion in the veins is the result. The walls of the blood vessels become expanded or constricted over different areas, thus the normal flow of blood is accelerated at first, but finally retarded, the venous congestion in the flushed face being an example of this.

Alcohol also acts directly on the composition of the blood, increasing the number of white blood corpuscles, but diminishing their uniformity and movement, and also their form. At the same time there is a great reduction in the number of the red blood corpuscles, thereby depriving the system of its usual supply of oxygen.

The action of alcohol on the nervous system is to destroy the nutrition of the nerve cells, causing a shrinking of the dendrites and fibrillæ, and also the destruction of the cell itself, resulting in degeneration of nerve fiber. This breaking up of the nutrient blood current favors the formation of toxins, which circulate in the blood and become the source of other poisons.

In addition to this, alcohol may excite and develop some latent predisposition, increasing the irritability of the nervous system, thus favoring delirium and delusions in any form. The toxins formed from the use of alcohol are slowly eliminated, and have the power of either depressing or exciting the nerve centers.

The removal of the alcohol is the first step in the treatment. The cessation of the delirium must not be expected to follow the removal of the spirits; on the contrary, twenty-four or forty-eight hours after the alcohol is withdrawn, the delirium and delusions will usually break out with greater intensity. The impression is created that this is due to what is considered a too sudden stopping of the so-called stimulant. But experience proves this to be wrong, the delirium coming on whether alcohol is slowly or suddenly withdrawn. In some instances the slow withdrawal of the spirits, when accompanied with sharp elimination through the bowels and kidneys, is followed by a subsidence of the mental disturbance.

This is entirely due to the removal of the toxins, and would have occurred sooner had the spirits been taken away at once.

Slowly reducing the amount of alcohol, giving narcotics, forcing the feeding with an idea of overcoming the supposed exhaustion, is extremely dangerous treatment. Recovery is delayed and complications encouraged, and a protracted convalescence always follows, with frequent fatal results from pneumonia and acute inflammations.

Alcohol is always a source for the development of toxins, which in turn produce delirium, recovery being impossible until the formation of theses poisons is prevented.

This part of the treatment must be carried out with vigorous efforts to remove the conditions which favor the growth of the toxins. After the spirits have been removed, one must give small doses of calomel with the salines until free catharsis is induced. Then continue the salines in decreasing doses, every other day, until the delirium subsides. The favorite saline in my practice is a combination of magnesium sulphate and potassium bitartrate, two parts of the latter to one of the former, given in small doses according to the conditions present.

Next in importance are hot-air and hot-water baths, hot packs followed by vigorous rubbing, and the old-fashioned sweat in steam by the use of hot irons placed in water under a blanket, all being useful means of promoting the elimination through the skin. This function must be stimulated daily so long as the delirium continues, also throughout convalescence, only less actively. Profuse sweating is of value, not only for its eliminative action, but because of its sedative effect of sudden drainage of the toxins through the skin, and the diversion of nerve energy.

Frequent sponging with hot salt water is another most effective measure, that in some instances approaches a specific.

The different textbooks mention elaborate prescriptions containing narcotics to produce sleep, and

many authors urge that sleep is the first essential to break up the delirium.

This has been found to be dangerous both in theory and practice. The system is already working under great embarrassment, the vital forces are lowered from the poisonous effect of the alcohol and the profound depression from the toxæmia.

All efforts to produce chemical stupor and narcotism are dangerous as they increase the toxins and diminish the power to overcome them. In persons unaccustomed to the use of spirits, anæsthesia for surgical purposes is dangerous under the most favorable conditions, and the peril is still further increased by the use of narcotics or sedatives, their administration having a tendency to increase the growth of toxins. All preparations containing opium, chloral, bromides, or the coal-tar derivatives are depressing and positively dangerous in the stage of delirium, and should seldom be resorted to.

For the craving for alcohol that follows the withdrawal in some cases, strong solutions of quassia or cinchona, given every hour, will soon break up this impulse and produce an intense disgust for spirits.

Many authors urge that alcoholics should be given, and also both solid and liquid food very freely, believing that the delirium is an evidence of starvation, and that it can be overcome by the administration of concentrated foods, beef tea, hot milk, cereals, and other nutrients. This is also not supported by experience and is literally a hazardous practice.

Assimilation and digestion are enfeebled, the blood is charged with toxins, cell metabolism is deranged, hence food given at this time assists in the growth of new toxins, and developing centers for the production of additional poisons. Beef tea, milk, and all liquid food are actually culture mediums for the formation of new toxins and perpetuation of the old ones.

Should the patient have a strong craving for food, great discretion must be used in the selection of the proper quantity; but total abstinence during the early stage is productive of the best results. When the delirium is subsiding, food may be given with extreme caution, the preference being for solids. The skill of the physician is often taxed when the patient is treated at home, the relatives and friends becoming unreasonable in their demand for more active medication; in such cases, phosphate of sodium granules, each ½ of a grain, will meet the indication. Strong, discreet nurses and attendants, who will guard the patient from personal injury and faithfully carry out the hydropathic treatment, are an absolute necessity.

Restraint depends largely on the patient, and in certain cases should be associated with as much liberty as possible; in others, where great exhaustion is present, the patient may be kept in bed, and given massage daily.

The surroundings must be absolutely quiet, and the patient should have no visitors. The delirium in most cases is self-limited, and will naturally stop in a few days; but in those cases in which it continues, the reasons for such should be inquired into and acted upon accordingly.

The condition of the heart during the stage of delirium rarely requires any treatment, but the administration of strychnine is of benefit for some unusual indication. Hot and cold water bags placed over the pericardium are much safer and more effectual as stimulants.

Ice on the nape of the neck is one of the most powerful excitants that can be used. The danger of heart collapse is small, and is in some cases seemingly imminent, but is usually functional and soon disappears.

When the delirium has subsided, different conditions of prostration follow, which are successfully treated by nux vomica and the preparations of arsenic. Strychnine is an excellent drug, but cannot be used in all persons for any length of time. There is in some persons an extreme sensitiveness to its physiological action, and this should be recognized.

Nux vomica is less active and can be used for a longer time. Cinchona in the form of an infusion is a valuable remedy, but should not be continued long, because of the abnormal appetite it is likely to create. Arsenic in small doses, used in conjunction with phosphate of sodium as tonic treatment, gives excellent results. The salines are better than bitter vegetable tonics, and should be given freely.

For the insomnia and various neuralgias that follow the subsidence of the delirium, baths, moderate exercise in the open air, and static electricity are the most valuable measures.

When sedatives are called for, some of the coal-tar derivatives are often useful.

The vegetable narcotics, of which lupulin, valerian, bull nettle, and the passion flower are examples, are often found to be efficacious. Preparations of opium are not safe, although, in some instances are very effective, but should always be concealed when administered. The acid phosphates are excellent in the convalescent stage, but care should be taken to use only the most simple formulas. Patients should remain in the open air as much as possible, and have "nerve rest" from all forms of excitement.

It is my practice during the stage of delirium to keep the patient in bed as much as possible; but when he insists on being up, to keep him in a state of sharp muscular activity by means of the baths, massage, walking, and other active movements.

When the delirium subsides, we should increase the muscle and nerve rest, but the bathing should be continued with light mental diversion. Static electricity given twice a day is very valuable. In my experience, the radiant electric-light bath at the beginning of the treatment has a most powerful action in promoting elimination and relaxation, which is followed by sleep, at first of short duration, then of increasing longer intervals.

In the convalescent stages, both the static electricity and electric light bath are the most valuable agents that can be used.

In one of the large public hospitals, patients with delirium are kept in the yard in the open air during the warm weather, with the apparent result of shortening the delirium.

It has been my experience that in selected cases the patient can be taken out for a walk with attendants, and after returning can receive a warm bath with excellent results.

Restraint in padded rooms, by straps and other appliances, is frequently the source of great exhaustion, and is fully as dangerous as restraint by chemical agents in the form of sedative and narcotic drugs.

Active exercise promotes excretion, and, with the aid of the baths and saline cathartics, helps to eliminate the toxins and restore the normal metabolism.

The evils to be avoided in all these cases are over-drugging and over-feeding, and the object sought for should be to assist nature to overcome the toxæmia and build up the deranged organism.

The Plague in Russia.—It is said that there has been an alarming spread of the plague in South Russia, according to dispatches from Lemberg, hundreds of fatal cases being reported in Moscow, Odessa, Kieff, Kherson, and other towns.

Spondylitis Deformans as a Form of Arthritis Deformans.—According to A. J. KUDRIASTOFF, spondylitis deformans is simply a form of arthritis deformans. His own observations have convinced him of the fact, and he believes that, though many authors have of late described the disease under different names, still they all must have meant the same affection. Senator says that the difference in the phenomena of the disease depends only on the difference of the affected parts, on the difference in the intensity of the disease with which the articulations of the extremities are affected, and on the presence or absence of the derangement of the nervous system. The author thinks that the limited or entire loss of motion of the vertebral column, more frequently its kyphotic curvature, occasionally the creaking sound felt in the vertebral articulations, the irregularity of the nervous phenomena of the spinal cord (with comparatively slight lesion of the latter), the marked atrophy of the corresponding muscles, the slow but gradually aggravated course of the disease, the limited or total loss of motion of the thorax, frequently the synchronous affection of other articulations, the occasional involvement of the heart; the action, cold, or injury as an exciting cause, the obstinate resistance to all treatment, and, finally, the deformed vertebræ felt on palpation—all these tend to prove that spondylitis deformans is simply a form of a well-known disease—Arthritis deformans.—*Vratch.*

Immunity in Infectious Diseases.—J. J. METCHNIKOFF concludes a long review of this subject as follows: (1) Immunity in infectious diseases is simply a case of ordinary absorption of organized elements; (2) The most general phenomenon in natural and artificial immunity is the process of phagocytosis; (3) The action of the phagocytes is due to their great sensitiveness, and their capability of digesting organized elements; (4) Intracellular digestion is performed with the aid of ferments, the chief among which are the cytoses; (5) These substances remain within the phagocytes, and not exuded into the plasma, they can pass into the fluids of the organism only after phagolysis, *i. e.* destruction of the phagocytes; (6) The digestive function of the cytose is aided by a substance more resisting to the action of the temperature, namely, philocytose (*substance sensibilisotrice or Zwischenkörper*); (7) Philocytose is a product of phagocytosis, and is exuded into the plasma in considerable amount; (8) Not only in natural, but also in some cases of artificial immunity, the organism is capable of resisting infection without the aid of the philocytose exuded into the plasma; (9) Antitoxins are, if not wholly, at least partially, products of the phagocytes; (10) Both natural and artificial immunity is to be looked upon as a cellular function.—*Russki Arkhiv Patologii, etc.*

Laryngeal Tuberculosis and Pregnancy.—A. KUTTNER submits the following propositions: With women in whom the prognosis is helpless, one should treat laryngeal tuberculosis only in the usual manner, and, if necessary, perform tracheotomy. With women in whom the general prognosis is favorable, one should wait so long as the laryngeal tuberculosis is quite slight (little erosion, a circumscribed ulcer). As soon as infiltration takes place, or the disease tends to become diffuse, one should inform the patient of the danger of her condition; and, after her consent is obtained, undertake tracheotomy as soon as possible; and should this not work favorably in a few days bring about artificial abortion. The earlier the pregnancy is interrupted, the more favorable are the chances for the mother, because the strain of labor is less the smaller the fœtus is, and also the loss of blood which occurs in artificial abortion is proportionately small. From the seventh month of pregnancy the chance for the mother becomes worse, because great exhaustion usually follows the strain of delivery. In advanced laryngeal tuberculosis it is advisable to undertake tracheotomy before delivery, or, at least, to hold one's self in readiness for its performance, in order to obviate the risk of sudden suffocation during delivery.—*Journal of Laryngology.*

The Personal Factor in Tuberculosis.—DYCE DUCKWORTH says that there are two pathogenic factors to be regarded in any case of tuberculosis: (1) The host, and (2) The infecting parasite. The younger pathologists are too apt to "reckon without the host." Physicians must consider the personal factor in disease. The modern doctrine that "scrofula is tuberculosis," the author absolutely denies, and maintains that it is possible to be scrofulous throughout life without becoming tuberculous. The essential character of scrofula is a textural vulnerability to irritation of all kinds, and especially to tuberculous invasion. Persons of gouty predisposition are thereby largely immunized against tuberculosis, the offspring of the gouty manifesting none of the peculiar delicacies of the strumous. Tuberculosis, when it occurs in the gouty, makes little progress, as a rule, and tends to obsolescence. Many of the preventive procedures against tuberculosis must relate to the personal factor, and our duty is to fortify the host against invasion, as well as to intercept and destroy the invader. The author protests against the modern idea of "curing" tuberculosis. All that we can do is to place the patient in conditions favorable to an arrest of the process.—*The Medical Press and Circular.*

Lessons to Be Learned from Vegetable Pathology.—JONATHAN HUTCHINSON calls attention to diseases in the roots and in the leaves of trees. If the whole tree is sickly, either there has been some starvation process at work in the supply of nutriment, or some general disease of the roots. The laws of competitive nutrition are often exemplified in vegetables, in congenital hypertrophies, for instance, and in the tendency in trees to produce a large number of seeds. Fungus growths attack roots and stems of trees and plants. Trees often have marked idiosyncrasies, as in the case of two oaks standing near each other, of the same age and species, and in equally good health. One of them keeps its leaves all through the winter. Disease and living parasites can be introduced upon plants, an instance of which is seen in the formation of galls from eggs deposited by a mother aphis at some point where a stem is about to bud. The plant mistakes the irritation produced by the eggs for the irritation produced by its own living seeds, and in the Norwegian spruce, for example, there is the production of something very like a cone.—*The Medical Press and Circular.*

Guaiacol Treatment of Laryngeal Tuberculosis.—J. H. COULTER advises that previous to the application the mucous surface should be cleansed with a warm alkalizing spray, not too vigorously applied. Then either by spray or swab apply a local anæsthetic of holocaine and antipyrin (1 per cent. of the former and 1½ per cent. of the latter). If, then, the guaiacol be immediately applied, or injected with care, the patient will suffer only a transient burning sensation of which few of them complain after the first treatment. He begins with a 20-per-cent. solution of guaiacol as an application, and, by treating the patient every other day, has had little difficulty in rapidly increasing the strength of the application, so that at the end of ten or fourteen days he could use an 80-per-cent., or, in some cases, a full-strength solution.—*Chicago Clinic.*

Bony Cysts of the Maxillary Sinus.—E. LAFARELLE reports two cases of this nature, both of which were cured by operation through the canine fossa. He regards as features peculiar to this condition the following: (1) The patient does not blow the nose and never discharges pus, at least not constantly; (2) Intranasal examination does not reveal any sort of irritation about the infundibulum or about the orifice of communication with the sinus; (3) An injection made through an alveolar opening returns by the same channel, and does not appear in the nostril.—*Revue Hebdomadaire de Laryngologie.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, December 14, 1901.

THE PATHOGENESIS OF TUMORS.

At the present time, for various reasons, more acute interest is taken in cancer than in any other disease. Its rapid increase in this and other countries, its occurrence among the royal families of Great Britain and Germany, and the awful nature of the malady are sufficient to account for the intense concern expressed everywhere by scientific men, with regard to its etiology, and the means of prevention or cure.

That cancer is really on the increase would appear to be an indubitable fact. Park has demonstrated that such is the case in New York State, and similar evidence comes from almost all the civilized countries of the world.

The Registrar General for Ireland reports that in that country the rate of mortality from cancer is higher than is the actual number of deaths from the disease.

The theory of a parasitic origin of cancer has received most favor with the majority of investigators, and it must be said that the preponderance of expert opinion in support of this view is justified by the result of the researches undertaken up to date.

Nevertheless, nothing has been definitely decided, and there are many earnest students who still hold that the arguments used and the testimony proffered by the upholders of the parasitic theory of malignant tumor require much further confirmation ere conclusions will be accepted as final.

Dr. Charles Powell White, Demonstrator of Pathology, Victoria University, Leeds, antagonizes the aforesaid theory, and in an able paper gives his ideas on the subject.

He believes, with Ribbert, that every cell has an inherent capacity for growth, which is held in restraint by the "tissue tension" of the part when this tissue is diminished, the capacity for growth is set free, and proliferation takes place. In short, Ribbert holds that fibrous tissue plays the chief part in tumor formation. Dr. White terms his explanation of cancer origin, "The doctrine of physiological equilibrium," an expansion of Ribbert's theory.

The argument is somewhat as follows: The axiom is laid down that the various parts of which the body is composed are normally in a state of equilibrium—stable, unstable, and neutral. If the position is stable, any disturbance leads to a position from which there is a tendency to return to the original position; if it is unstable, any disturbance leads to a position in which the tendency is to fall away from that position, while the state of neutral equilibrium does not occur in the living body.

According to Dr. White's views, the essential factor in tumor formation and other progressive processes does not lie in external agents, but the condition of the body which he denominates unstable equilibrium.

Dr. White summarizes in part thus:

Tumors, as a rule, take their origin from normal tissues or cells; occasionally, however, they may start from one of Cohnheim's rudiments. The extrinsic causes of tumor formation, as far as they are known, do not differ essentially from the extrinsic causes of inflammation, etc. In the case of tumors, however, we generally cannot determine the extrinsic causes, and, on the views that I have propounded, this is intelligible, that the parts being in an unstable equilibrium, a very slight cause would suffice to disturb the position.

The essential difference between the progressive and reparative processes lies in the condition of the body. In the one case the parts are in unstable, in the other they are in stable, equilibrium. It is not possible, at the present day, to say in what this difference actually consists.

The gist of Dr. White's argument would seem to be that, when the body is in that condition which he terms unstable equilibrium, either the progressive or reparative processes may cause cancer, and that the origin of the disease depends essentially upon the condition of the body, and not upon external agents.

As remarked before, these views run counter to the parasitic theory held by the majority of those who have made long and deep researches into the matter, and which is, without doubt, the strongest theory of the origin of cancer yet advanced. But at the same time no absolutely definite proof has been brought forward that the disease thus originates. Until this has been done, it is open to any one to propound views; and, moreover, a successful ultimate discovery is likely to be more quickly arrived at by a free ventilation of the subject in medical journals and at medical meetings and by painstaking laboratory investigations from every conceivable standpoint.

INTUSSUSCEPTION.

THE slipping of one portion of intestine into another adjacent portion can scarcely be considered a common disorder in children, but the need for treatment, when it arises, is so urgent that the condition is one concerning which the practitioner cannot be too well informed. In many respects, the attitude of the physician with respect to intussusception has become much like that with respect to appendicitis and other forms of intestinal obstruction, and while, like the latter, it may in its incipiency present features of a medical aspect, the condition is one in which the advice of a surgeon should be had early in order that if operative intervention become necessary, it can be promptly instituted. The essential cause of intussusception is excessive activity on the part of the muscular coat of the intestines, the vermicular action of one portion of the bowel carrying it into another distal portion, in which it becomes grasped

by the contraction of the circular muscular fibers. In an address delivered recently before the North Wales Branch of the British Medical Association, Mr Edmund Owen (*British Medical Journal*, September 7, 1901, p. 573) described the symptomatology of intussusception as follows: "A healthy infant or young child is suddenly seized with a pain in the abdomen. He rolls, screaming, on the floor or in his cot and is found 'doubled up' and much collapsed. Probably he vomits, and in a straining act of defecation he passes a little mucus or some mucus and blood with scanty liquid fæces. (Were his trouble due to a twist or a band, nothing would pass per anum.) There may be no distention of the bowel, for the case is not one of actual intestinal obstruction; there may even be some diarrhœa. The distress comes on in paroxysms and between whiles the little patient may lie quite placidly. So the surgeon must sit by and watch. If the abdomen remains flat, there may be no difficulty in making out the presence of a 'thickening' or a 'lump' in the region of the ascending colon. The textbooks, with their customary unanimity, speak of the little lump as 'sausage shaped.' This is somewhat unfortunate, for that striking simile has left so deep an impression on the student that when he gets into practice he may hardly dare to make the diagnosis of intussusception in absence of the 'sausage-shaped' tumor; and if he waits for the mass to assume this shape before venturing on his diagnosis, he may be doing irretrievable harm to his patient and spoiling the chance of the ultimate success of a surgical operation." Mr. Owen is an advocate of prompt surgical intervention in the treatment of intussusception, and is of the opinion that it is "nothing less than a calamity that physicians have every now and then managed to chase back an intussuscepted piece of bowel by using an enema." He goes on to say that "it would be an interesting speculation as to the percentage of cases in which the receptive piece of bowel has been ruptured or in which the child has died unrelieved." As Mr. Owen points out, the results of abdominal section for intussusception have hitherto been highly unsatisfactory, but this is largely due to the fact that operation has been undertaken only after the child has been subjected to inflations or injections and other manipulations. Mr. Owen sums up his argument by maintaining that whether strangulation of the intestines is due to an ensheathing piece of bowel or to the neck of a hernial sac, the effects are much the same, and that delay in affording relief is likely to be fatal. Finally, he contends that the best way of affording prompt and certain relief is by the surgeon cutting down to the seat of strangulation and putting it right in a proper surgical way.

Mr. Bernard Pitts (*ibid.*, p. 574), in a paper read before the recent meeting of the British Medical Association, recommended the following plan of treatment for cases of intussusception: (1) Try inflation only when the case is seen within a few hours of the onset and it is not of a very acute character. In the great majority of hospital cases, it is better to open the abdomen at once. (2) Inflation may be tried in certain other cases for the purpose of reducing the main portion of the intussusception and enabling the incision to be made directly over the cæcum. (3) When reduction is found impossible in chronic cases, a resection may generally be done through an incision in the ensheathing bowel. (4) In a few cases and especially if gangrene is present or the condition of the bowel requires its removal, a wide resection should be undertaken as rapidly as possible and the ends brought outside the abdomen. Continuity should be restored at a subsequent operation. (5) In exceptional cases of enteric intussusception, resection and immediate restoration of continuity afford the only chance. Mr. D'Arcy Power (*ibid.*, p. 579) stated that although formerly an advocate of irrigation of the bowel, greater experience has taught him that this method is not to be relied upon. It is now his practice to perform abdominal section at the earliest possible opportunity, reducing the intussusception if possible without bringing the tumor into the wound, though he has no hesitation in making a large incision and bringing the intussusception outside the abdominal cavity should there be the least difficulty in reduction. Mr. William McA. Eccles (*ibid.*, p. 580) expressed the opinion that providing the surroundings of the patient are satisfactory, the results of the present day show that immediate coeliotomy with a view to reduction of an intussuscepted bowel is clearly indicated. Mr. A. H. Tubby (*ibid.*, p. 580) held that in all but possibly the earliest cases—that is, in those of a few hours' duration—the patient stands a much better chance if abdominal section is performed at once. Mr. Frederick Eve (*ibid.*, p. 582) summed up the arguments against the employment of inflation or injection as follows: (1) Injection or inflation is rarely efficacious. (2) Injection or inflation is not infrequently followed by an illusory or partial reduction. So-called recurrence of the displacement is inevitable, and the consequent delay in performing the operation usually leads to a fatal result. (3) Injection or inflation is haphazard and therefore unscientific. Neither can be expected to influence an intussusception commencing in the small intestine. It has been shown experimentally that as regards young children the ileocecal valve is so competent in more than half the cases that it will not permit sufficient air or water to pass it to reduce an artificial invagination of the ileum. It is thus obvious that the consensus of English opinion is against temporizing measures in the treatment of intussusception of the bowel and in favor of early operation.

BRITISH AND AMERICAN NAVY RATIONS.

So to feed a navy as to keep its men in a good state of health and render them efficient fighting machines, is a more difficult problem successfully to solve than with an army. There has been for some time among the crews of British war vessels much dissatisfaction with the dietary table. A committee, therefore, was appointed to probe the matter, and to suggest improvements. This committee has just ended its investigations, and has handed in its report, which is worthy of a careful study by those connected with, and interested in, the navy of this country.

In the first place, the composition of the committee will probably arouse some surprise, as with one exception its members were all laymen. The inclusion of an expert, who could have passed an authoritative opinion on the value of the food regarded from a scientific nutritive standpoint, would have added weight to the deliberations. Notwithstanding this omission, the conclusions reached by the com-

mittee seem to have given general satisfaction, tinged, it may be said, with judicious criticism.

From a perusal of an abridged copy of the report, it will be gathered that biscuits are peculiarly distasteful to the British man-of-war's man, yet the committee could not see its way to recommending the serving of fresh bread at sea, although it is claimed that the baking of this article of food presents no insuperable difficulties on board a modern battleship. Potatoes, it seems, are in great favor with sailors of the Anglo-Saxon race, and the committee recommended that the supply of the vegetable should be increased.

The point that will probably most forcibly strike an American naval man when reading the revised diet table of the British navy is its lack of variety and the apparent inadequacy of the fresh meat supply. In time of war, dependence will be placed upon salt meat and preserved foods, and as a correspondent to the *Lancet* cogently remarks, "He sees no reason why salt meat should be regarded as a *sine qua non*, nor why slightly corned meat should not be substituted or used in conjunction with the sailor's hard tack."

Again, it will appear somewhat curious to an American that scarcely any of the English war ships are supplied with refrigerating chambers. This circumstance, however, is not touched upon by the committee.

So far as weight is concerned, the new daily ration of the British navy compares well with the old ration, the former weighing four pounds and the latter three and a quarter pounds.

The British seaman's diet as now constituted contains: Proteids, 8.37 ounces a day; carbohydrates, 19.83 ounces a day; fats, 3.63 ounces a day; salts, 1.27 ounces a day. This combination of the ingredients necessary to keep a man in vigor would appear to be in proper proportions, and compares favorably with the food usually eaten by those who are engaged in hard manual labor.

Some three years ago, the United States navy adopted a new diet table, which, for amount, variety, nutritive and sustaining qualities, cannot be equalled by any navy of the world. For each meal in the table, running through a week, says the *Army and Navy Journal*, the precise amounts of albuminoids, carbohydrates, and fats were arranged. The full diet table is as follows, for one day in the week (the number after each article relating to ounces): Breakfast: coffee, 1; bread, 4; butter, 1; milk, 6; sugar, 1; oatmeal, 1; beefsteak, 6; Dinner: rice soup, 8; bread, 4; roast beef or roast or boiled fowl, 8; potatoes, 8; other vegetables, 6; pickles, 1; bread pudding with sauce, 6; or custard frozen, 8; fresh fruit, 6; Supper: tea, ¼; bread, 6; butter, 1; milk, 2; sugar, 1; cold roast mutton or cold roast beef, 4; stewed, dried fruit, or apple sauce, 4.

The staples, coffee, bread, butter, milk, sugar, and fresh and dried fruit, are the same for each meal; but there is a daily variety in meats and other articles, for breakfast, dinner, and supper.

A comparison between the American navy diet table and that of the British will, of course, be immensely to the advantage of the former. It may be borne in mind, however, that the British Government, in dealing with both its soldiers and sailors, eschews luxury for them, and merely endeavors to provide a wholesome diet at a cheap rate. Whether, when the recommendations of the committee are carried out, this object will have been fully attained, remains to be proved.

To the ordinary observer it might appear that the committee would have done well to recommend the serving of fresh bread at sea, the construction of refrigerating chambers on battleships for the preservation of butter, meat, and other articles of diet, and to advise that salt meat should not be wholly relied upon as the staple of diet in time of war.

It is easy to criticise at a distance, and probably the committee, who were all practical men, were thoroughly well acquainted with the idiosyncrasies of the British naval sailor, who, with the usual conservatism of the race, might strongly object to his modicum of salt beef being decreased, and might regard with scorn the Sybaritish fare of his American brother.

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

THE ratio of admissions to the sick list per 1,000 of strength was for 1899, 783.03; and for 1900, 824.12; so that, comparatively, there was more sickness in the navy in 1900 than during the previous year.

The total number of admissions for all causes was 18,936; of these 15,829 were for disease, and 3,107 for injury, giving a ratio per 1,000 of strength of 688.90 and 135.22, respectively.

During the year there were 211 deaths; the death rate per 1,000 of force being 8.88. The mortality rate from all causes for 1899 was 7.35 per 1,000.

The admissions to the sick list during the year included 1,699 cases of epidemic catarrh, 983 of malarial diseases, 963 of wounds, 902 of diarrhœal affections, 828 of rheumatic affections, 336 of dengue, 246 of alcoholism, 195 of dysentery, 175 of typhoid fever, 160 of measles, 132 of mumps, 128 of heat stroke, 117 of pulmonary tuberculosis, 100 of organic heart disease, 99 of pneumonia, 40 of nephritis, 37 of rubella, 10 of smallpox, 2 of yellow fever, and 1 of bubonic plague.

Epidemic catarrh, which on almost every station and ship caused more admissions than any other infectious disease, was especially prevalent on the North Atlantic coast. The returns, however, according to the report, do not indicate that the unusual number of cases was due to conditions peculiar to the naval service, but rather that it was incident to a pandemic spread of the disease.

Dysentery while accounting for more admissions than in 1899 was the cause of but 5 deaths; of the 10 cases of smallpox reported 5 proved fatal.

In the report of Dr. John C. Boyd, medical inspector United States Navy, of the flagship *Kearsarge*, are some very interesting and instructive remarks on the navy ration question.

Dr. Boyd adds his testimony to that of many others with regard to the nutritive value and sufficiency in amount and variety of the several food elements which collectively constitute the ration now issued by the Navy Department, and he also advocates that the general messing practised on the *Kearsarge* should be substituted for the individual messing system which is in general use throughout the service.

Dr. Boyd is particularly insistent that well-trained

cooks should be employed on board the vessels of the United States Navy, and argues that unless this be done, however good the ration may be, it will in many instances be spoiled or its nutritive value impaired by bad cooking. The remedy suggested for this too frequent occurrence is that some well-defined plan should be adopted for instructing a certain number of the enlisted force in the special knowledge pertaining to the duties of ship's cook.

Some of the special reports appended to the report itself contain matter of much value.

Dr. George A. Lung, surgeon U. S. A., gives a short history of the China Relief Expedition, in which his regiment of marines took part. The health of the American troops engaged in this expedition seems to have been fairly good, the most prevalent complaints having been diarrhœa and heat prostration. After reaching Peking many new cases of fever appeared, but to no very troublesome degree; neuralgias were also common, especially sciatica.

Dr. Lung was greatly impressed with the Japanese troops, both as regards their mental and physical qualities.

The report of the Surgeon-General of the Navy is, upon the whole, a satisfactory document, and is a plain evidence of the fact that the men of the United States Navy are better cared for from a medical and sanitary point of view than those of any other navy of the world.

Municipal Infant-Feeding Bottles.

Municipalities in different parts of the world are taking paternal care of those who are so fortunate as to live under their control. The city fathers in many large centers of population supply the inhabitants with gas, water, means of locomotion, and even with dwellings at a cheap rate, and, in addition to these material benefits, provide instruction and amusement for the mind.

Battersea, a large district of London, chiefly populated by the laboring classes, and which was a pioneer in this new movement, has recently decided to make another innovation, and to supply nursing bottles to those persons who apply for them. The infant mortality there has been greatly on the increase within the past few years, due, it was believed, to impure milk and unclean bottles. Having arrived at this conclusion, the municipal council of Battersea at once resolved to take steps to meet the situation, and, according to the New York *Press*, are about to open a station at which the best cow's milk obtainable will be bottled and distributed among the poor of the locality. Nine hermetically sealed nursing bottles of sterilized milk will be supplied daily to each customer at a charge of a little over thirty cents a week, and the station will collect the used bottles every day, and supply clean ones in their place. The nine bottles for each day will be packed in a basket, six for use in the day, and three in the night.

Undoubtedly, there is "method in the madness" of Battersea, and although the scheme savors more of maternalism than of paternalism, yet, if carried out efficiently it will be the means of checking the infant death rate to a very appreciable degree. Contaminated milk is the cause of more deaths among infants than perhaps any other one cause.

It may be said that the plan just adopted in Battersea has been tried in Fécamp, France, with conspicuous success, the death rate among infants being reduced in one year from 157 to 103 per thousand.

Malaria in Buffalo.

Malaria, like the poor, but to a lesser degree, is always with us, as is also the mosquito. Banish the mosquito, and it is asserted, the malaria will vanish. Exterminating war has been declared on the mosquito, wherever it exists, and praiseworthy though futile efforts have been put forth to abolish the troublesome and disease-bearing insect.

It is to be regretted that Americans have been backward in this good work, but the deductions made by Major Reed and associate workers, that mosquitos are directly responsible for yellow fever, will presumably hasten on a crusade against mosquitos throughout all lands, under the control of the United States.

Dr. Irving P. Lyon and Mr. Alfred B. Wright of Buffalo have been pursuing investigations of ascertaining whether Anopheles are present in Buffalo, and also, the frequence of diagnosis of malaria by general practitioners of medicine.

From May 12–October 7, 1900, 374 mosquitos were caught within and near Buffalo, in places to which public report attached a reputation of being malarious. Of these 374 specimens, every mosquito belonged to the genus Culex, and not a single example of Anopheles, the malaria-bearing variety, was found.

With regard to the occurrence of malaria in Buffalo, the experience of a number of physicians in that city, by blood examinations, was unanimous against the autochthonous development of malarial infection in and about Buffalo.

The foregoing investigations only go further to prove, that, where the Anopheles is absent, there is no malaria.

The scientists of Buffalo have, however, set those of other cities of America an excellent example, which, if followed, would go far toward increasing the future knowledge of malaria distribution and of abolishing, at any rate, from this country that disease.

Improvement in the Medical Corps of the Navy.

In the recent report of the Secretary of the Navy, the benefit to the Medical Department of the navy by the greater liberality of Congress toward this department in the matter of rank and pay is thus noted: "The passage by the last Congress of the act giving assistant surgeons in the navy the same rank as assistant surgeons in the army has proved of great benefit to the corps.' A very desirable class of young medical men is now seeking admission, and the number of vacancies has been reduced from seventeen at last report to four, and it is probable that these will soon be filled."

The Violet Cure of Cancer.

A story—or rather one that reads more like a fairy tale—has been going the round of the English lay journals to the effect that a lady of title whose name is of no consequence, has been cured of cancer by the application of fomentations of macerated green leaves of the violet plant.

The affection is stated to have exhibited itself in the form of a tumor of the throat, and its malignant nature was made certain by microscopical examination of a small portion removed.

The lady was so grateful for the supposed cure of a disease which invariably terminates fatally that by way of demonstrating her gratitude for her unexpected recovery, she caused to be printed and distributed leaflets describing the treatment.

There can be no doubt that the case was one of mistaken diagnosis, notwithstanding the assertion that the malignant character of the tumor was proved by the microscope.

The violet leaf has long borne the reputation of

being a valuable therapeutic agent. The early Normans were implicit believers in its efficacy, and used it for a variety of complaints, dyspepsia among the number; but even in the age of superstition and credulity, in which they lived, there is extant no record that the wise men in medical affairs placed faith in any preparation of violet leaves as a cure for cancer. Such ignorance has been reserved for the cultured members of the 20th century society to display.

The Preservation of Forests.

The part of President Roosevelt's message referring to the preservation of forests will especially interest medical men, and those who concern themselves with the health conditions of the country.

In the MEDICAL RECORD, January 27, 1900, this subject was treated at some length in an editorial, and the opinion was tendered that, if the wholesale destruction of forests, as at the present time carried on, should be continued, serious results to health would follow.

Trees are not only to be desired from a standpoint of beauty, but are also the chief factors in distributing and regulating the rainfall, and in dry seasons by their action in holding back evaporation, preserve the water supply, and thus, in the President's words, "Forest conservation is an essential condition of water conservation. A country denuded of trees is in the natural order of things an unhealthy country.

President Roosevelt recommends that for the salvation of the forests the power which is now diffused among three or four bureaus, should be centralized in the Bureau of Forestry, and with this bureau alone should rest all the work relating to the forest lands of the United States.

For economic as well as for hygienic reasons, the protection of forests will recommend itself to the intelligence of Americans.

Sulphur in the Treatment of Dysentery.

Dr. G. B. Richmond, late of the Imperial Yeomanry Hospital, Pretoria, relates in the *Lancet*, November 23, his experience in the use of sulphur in the treatment of dysentery. He states that he had tried all the recognized remedies for the disease with no success, and had paid special attention to the dictum of the late Sir William Gull, that the only effectual treatment of dysentery was "rest, warmth, and ipecacuanha."

The trial of sulphur as a therapeutic agent was suggested to Dr. Richmond on the analogy of the treatment of anthrax by sulphur advocated by Mr. Arbuthnot Lane.

The dose administered was 20 grains of sublimed sulphur combined with 5 grs. of Dover's powder, four to be given hourly. The sanguine expectations of the author were more than justified by the results, for in every case treated by sulphur a cure was effected, and, further, there seemed to be no tendency to relapses or chronic conditions of alternating diarrhœa and constipation; and furthermore there was no vomiting as with ipecacuanha, and therefore no necessity to starve patients.

The precise mode of action, says Dr. Richmond, of sulphur in the intestines is more or less a matter of conjecture. It is, however, reasonable to suppose that sulphuretted hydrogen and other sulphur acids are formed, and inhibit the growth of the microorganism of dysentery. It is perhaps a justifiable speculation, that the dysentery of South Africa is like the epidemic dysenteries of Japan and of the Philippines, shown by Flexner to be due to a specific bacillus, morphologically approaching the type of the bacillus typhosus.

Taking into consideration the great prevalence of dysentery in the Philippines, experiments with sulphur in the treatment of the disease would, in the first place, show whether its administration bore as good results there as in South Africa, thereby tending to prove the identity of the malady as met with in the two localities; and, secondly, if the treatment were found as effectual as Dr. Richmond asserts, it would be a valuable means of checking the inroads of dysentery among the American troops in the islands of the Far East.

New York Street Cars in Winter.

Recently several persons have written to the New York *Herald* denouncing the faults of the system of street-car locomotion in vogue in this city.

With many of the points urged against the methods of the street-car corporations as regards the conduct of their public conveyances, the MEDICAL RECORD is in complete accord. In an editorial published on December 9, 1899, the subject was discussed from the standpoint of public health.

A part of this editorial runs thus: "The desiderata in a public conveyance are that it should be suited to the weather; in the winter warm and closed, but well ventilated: in the summer open and airy. It should admit of being easily and quickly closed, and *vice versa;* and should at all times be as free from draughts as possible. The car will not be satisfactory unless it can readily conform to the requirements of a season fickle at all times of the year."

Putting aside the question of overcrowding, a serious and important one, and which could be remedied if the car corporations so willed, Do the street cars of New York fulfill the conditions mentioned above? No one will be found bold enough to assert that they are warm and closed, but well ventilated in the winter. They are, on the contrary, as a general rule, distinctly cold and airy.

Surely, improvements might be effected in this respect, and locomotion by means of cars in New York be converted into a pleasure, rather than, as is now too frequently the case, an ordeal to be dreaded.

Health Officer for Buffalo.

Dr. Ernest Wende has made for himself an enviable record since he was first appointed Health Commissioner of Buffalo.

According to an article in the December number of the Buffalo Medical Journal, he has by his energetic methods almost freed the city from typhoid fever. The milk ordinances, which besides paying for themselves, are sources of revenue, and are serving as models for other cities, were enacted at the instance of the present Commissioner of Health. The establishment of free public baths was due to his foresight. Registration of contagious diseases to the milk route is yet another of his measures.

Dr. Wende's chief fame, however, as a sanitary reformer will rest upon his action in doing away with long-tube nursing bottles, and the consequent saving of the lives of thousands of infants. This plan has been adopted in a large number of American cities as well as in Great Britain and other civilized countries.

The MEDICAL RECORD has at all times contended that politics should have nothing whatever to do with the health boards of cities. It is monstrous that, owing to political influence, inferior men should be foisted upon a health department, and that by these means its efficiency should be lessened, and that the health of a large community should be endangered.

It is to be hoped that the people of Buffalo will recognize the great services Dr. Wende has rendered them, by exerting moral pressure upon the new Mayor to induce him to reappoint the outgoing Commissioner of Health.

News of the Week.

Smallpox in the Philippines.—Owing to the extensive prevalence of smallpox in several of the Philippine Islands, the health department has requested the Commission to prepare a law enforcing compulsory vaccination everywhere in the archipelago.

Sanitary Regulation of Manila.—A corps of sanitary inspectors has just been established in Manila, composed of one Chief Health Inspector, two Medical Inspectors, twelve Chief Sanitary Inspectors, and thirty-three Sanitary Inspectors. All members of the corps are required to wear uniforms. The rules governing the operation of the corps require the frequent and careful inspection of all buildings in the city. The Chief Health Inspector is also required to keep an accurate list of all saloons, gambling houses, hotels, restaurants, boarding and lodging houses, tenements, theaters, opium dens, houses of prostitution, markets, schools and public places of all kinds.

Whooping Cough in New Guinea.—In his annual report to the Colonial office, the Governor of British New Guinea says that two children who were brought to that colony from Samar, while suffering from whooping cough, started an epidemic of the disease which has raged with great fury during the past year, and has been attended with a remarkable fatality.

Search for the Yellow-Fever Germ has been going on for some time at the Army Medical Museum at Washington, under the direction of Major Walter Reed and Dr. Carroll, but thus far the search has been fruitless. The investigation has included examination of the blood of yellow-fever patients, and also of infected mosquitos, but in neither has it been possible to identify any organism as the specific hæmatozoon of the disease.

An International Sanitary Congress will be held in Havana on February 15, 1902, and following days. This is a sequel to the pan-American Medical Congress held in the same city last February, and was decided upon then on the recommendation of Dr. Wilde of the Argentine Republic and Surgeon-General Wyman of the U. S. Marine-Hospital Service. Twenty-five governments, including the Danish, French, Dutch, and English West Indies, and the Dominion of Canada, have been invited to take part, each sending three delegates—a physician, an engineer, and a commercial representative. The questions to be considered by the Congress are: (1) Sanitary condition of the commercial ports in America; (2) General measures of sanitation applicable to all ports, and special measures applicable to the individual ports; (3) The special modes of propagation of malaria, cholera, yellow fever, typhoid fever, plague, typhus fever, smallpox, filariasis, measles, scarlet fever, diphtheria, leprosy, and tuberculosis; (4) Measures necessary to be taken in each port in order to prevent an outbreak of any of the diseases mentioned, and to prevent their transmission to other countries; (5) Modes of propagation of the following epizootic diseases: glanders and farcy, plague, Peruvian verrugas, contagious pleuropneumonia, anthrax, Texas fever, rabies, aphthous fever, scabies, swine plague, actinomycosis, murrain, pink-eye, cerebrospinal meningitis, tuberculosis, and epidermic lymphangitis; and the means of preventing the occurrence and spread of these affections in animals; (6) In case quarantine is accepted as one of the most efficacious means at present known to us for preventing the introduction of contagious diseases among men and animals to determine its duration and conditions as regards each of these affections, in order to interfere as little as possible with commercial intercourse; (7) Means of examination of men and animals and of inspection of baggage and goods when infection is suspected; (8) Transmissibility of diseases by means of cargoes and suitable measures of disinfection. The languages allowed in the discussion will be Spanish, Portuguese, French, and English. The president of the committee on organization is Dr. Juan Santos Fernandez, and the secretary is Dr. Tomás V. Coronado, both of Havana.

Tent Life for Consumptives.—A sanatorium has recently been established near Denver, where the open-air treatment is carried out fully, there being no house at all for any of the inmates. Each patient has a roomy tent, which cannot be too tightly closed, plenty of warm day and night clothing, and a small stove in which a fire can be lighted in extreme weather.

Generous Bequest to a Hospital.—By the will of the late Samuel B. Huey, President of the Board of Public Education, the sum of $10,000 is bequeathed to the Presbyterian Hospital of Philadelphia for the foundation and support of a free private room for any trustworthy man or woman whom the trustees may designate.

College of Physicians of Philadelphia.—At a stated meeting held December 4, Dr. F. Savary Pearce read a paper entitled "Association of Hysteria with Insanity." Dr. Arthur Van Harlingen read a paper entitled "Recent Views on the Origin and Nature of Herpes Zoster." Dr. David Riesman read a paper entitled "Albuminous Expectoration After Thoracocentesis," reporting an illustrative case. He attributed the complication to œdema of the lung as a result of irritation.

University of Pennsylvania.—Announcement has been made of the reception of a contribution of $25,000 made by Keasbey and Mattison to the fund for the erection of the new medical laboratories. The sum of $4,000 has been received from Mrs. Thos. K. Conrad, completing the sum of $10,000 necessary to establish a fellowship in the department of physics to be known as the John Fries Frazer Fellowship. Dr. John S. Wentz has made a contribution of $5,000 for the purposes of the new engineering department.

Philadelphia Hospital.—At the fifteenth annual banquet of the Association of Ex-President and Resident Physicians of the Philadelphia Hospital on December 3, toasts were responded to as follows: The Blockely Prodigy, by Dr. M. J. Keeney; The Blockely Man in Country Practice, by Dr. William T. Sharpless; The Blockely Man in the Medical Society of the State, by Dr. Thos. D. Davis, and A Blockely Inspiration, by Dr. J. B. Walker. Remarks were made also by Drs. E. W. Holmes, J. P. Tuttle, and R. C. Norris.

A Memorial Children's Hospital in St. Petersburg.—The corner-stone has been laid in St. Petersburg of a new children's hospital, established to commemorate the coronation of the Czar and his Consort. The hospital, which will be built and maintained by the government, is to be made up of separate partitions, and will have accommodations for four hundred patients.

The California Northern District Medical Association.—At the eleventh annual meeting of this society, held at Sacramento on November 12, the following officers were elected: *President*, Charles R. Harvey of Stockton; *First Vice-President*, John T. Jones of Green Valley; *Second Vice-President*, Moses W. Ward of Woodland; *Third Vice-President*, Edward W. Twitchell of Sacramento; *Secretary*,

Elmer E. Stone of Marysville; *Treasurer*, Oscar Stansbury of Chico.

Complaint of Lepers at Molokai.—Several of the lepers in the isolation colony at Molokai have written to the papers charging the Hawaiian Board of Health with neglect and misdemeanors in connection with their supply of food and water. They ask for a State commission to investigate.

A New Russian Medical Journal.—When the late Professor Manassein died, it was learned with surprise and regret that he had left explicit directions that the publication of *Vratch*, a journal of which he was the founder and editor, shall be discontinued with the closure of the volume current at the time of his death. The journal will, therefore, die with the present year, but its place will be taken by a new one called *Russki Vratch*, or "Russian Physician," the first number of which is dated October 27, 1901. The title page bears the announcement that the journal is founded in memory of V. A. Manassein, and is edited by Professor V. V. Podvyssotski of Odessa, and Dr. S. V. Vladislavlev of St. Petersburg. The journal resembles its predecessor in general appearance and arrangement of contents, but contains a new feature in a list of articles, with brief explanatory notes, appearing in all the principal medical journals of Europe and America.

Water Reservoirs for London.—Rapid progress is being made upon the new reservoirs at Staines, Middlesex, for the supply of London, and it is anticipated that they will be completed in about two years. The reservoirs are approximately four and one-half miles in circumference, and their capacity will be 33,000,000,000 gallons, a sufficient supply to serve the district catered for by the water companies, to whom they belong, for 100 days. The reservoirs will be supplied from the flood water of the Thames.

S. R. Smith Infirmary, Staten Island, N. Y.—Dr. William B. Pritchard of New York was appointed by the Board of Trustees, at their November meeting, Consulting Neurologist to the S. R. Smith Infirmary, Staten Island.

The Medical Society of the State of New York.—The annual meeting of this society will be held at Albany on Tuesday, January 28, 1902, and the two following days. The scientific part of the program is being prepared by the Business Committee, which consists of Dr. Nathan Jacobson, 430 S. Salina Street, Syracuse; Dr. George R. Fowler, Brooklyn, and William C. Krauss, Buffalo. Members and delegates desiring to read papers will please communicate with the Chairman of this Committee. A rebate will be given by the railroads to members and delegates attending this meeting, but it is necessary, to obtain this rebate, that a certificate be obtained from the ticket agent at the starting point, which the agent will give for the asking.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy for week ended December 7, November 29—P. A. Surgeon H. H. Hass, detached from Norfolk Navy Yard, and to the *Kearsarge* for duty with the marine detachment. November 30—Assistant Surgeon F. M. Furlong, when detached from New York Hospital, ordered home on sick leave for two months. December 4—Assistant Surgeon P. E. McDonnold, detached from the *Constellation*, when discharged from Naval Hospital, New York, and ordered home with one month's sick leave. Assistant Surgeon W. M. Garton, detached from the Naval Academy and ordered to the Naval Hospital, New York. December 5—Assistant Surgeon J. B. Dennis, detached from the Naval Hospital, New York, and ordered to the Naval Academy, upon reporting of relief.

The Arizona Board of Medical Examiners announces that the next meeting of this board will be held at Phœnix, on the first Monday in January, 1902. The law requires applicants to present a diploma from a recognized medical college together with certificates of moral character, and to pass an examination before the board. These examinations are written and require two days. Communications should be addressed to Dr. William Duffield, Acting Secretary, Phœnix, A. T.

Dr. E. L. Trudeau has been elected trustee of Columbia University to fill the place of the late Dr. William H. Draper. Dr. Trudeau is a graduate of the medical department of the University in the class of 1871.

The Missouri State Conference of Charities and Correction.—At the second annual conference, held in Columbia on November 18 and 19, the following officers were elected: *President*, Dr. R. H. Jesse, President of the State University, Columbia; *Vice-President*, Dr. E. C. Runge, St. Louis; *Secretary*, J. M. Hanson, Kansas City; *Treasurer*, L. D. Drake, Boonville.

The "American Journal of Anatomy."—We have received the first number of this new journal, dated November 7, 1901, which has been founded to collect into one place, and present in a worthy manner, the many researches from American investigators, now scattered through many publications at home and abroad. It will be issued in quarterly numbers, each of about one hundred and twenty-five pages, and is published in Baltimore. The editorial board consists of Drs. Lewellys F. Barker of the University of Chicago, Thomas Dwight of Harvard University, Simon H. Gage of Cornell, G. Carl Huber of the University of Michigan, George S. Huntington of Columbia University, Franklin P. Mall of Johns Hopkins University, Charles S. Minot of Harvard University, George A. Piersol of the University of Pennsylvania, and Henry McE. Knower of Johns Hopkins University, the last being secretary of the board. This first number contains articles on "Development of the Limbs, Body-wall, and Back in Man," by Charles Russell Bardeen and Warren Harmon Lewis; "The Intra-lobular Framework of the Human Spleen," by Preston Kyes; "Studies on the Neuroglia," by G. Carl Huber; "The Normal Histology of the Human Hemolymph Glands," by Aldred Scott Warthin; and "On the Morphology of the Pineal Region, Based Upon Its Development in Acanthais," by Charles Sedgwick Minot.

A New Building for the German Hospital.—The new annex for private patients of the German Hospital was opened last week. August Zinsser, Chairman of the Building Committee, presented the building to the President of the Trustees, Theodore Kilian, who made a speech of acceptance. Addresses were delivered by Carl Schurz and by Randolph Guggenheimer. The new annex is a five-story brick building, fronting 80 feet on Seventy-seventh Street and 45 feet on Lexington Avenue. It has accommodations for seventy-five patients.

Smallpox is spreading widely in various parts of the country. In the Oranges in New Jersey, there were thirteen cases a week ago, and twelve cases in Sayresville. In Philadelphia, 304 cases of the disease were reported during November, a greater proportion of these being among the well-to-do than the very poor. The Board of Health is compelling all children attending public or private schools to be vaccinated

and the Director of Public Safety has issued a circular addressed to the householders of the city urging upon them the advisability and necessity of vaccination and of revaccination for all persons who have not been successfully vaccinated within five years. The city has organized at corps of physicians who will call at every residence, and vaccinate free of charge, if so requested, all the inmates. At Harvard University, President Eliot has signed a notice advising all students to be vaccinated, if they have not been successfully vaccinated within seven years. The outbreak of tetanus following vaccination in Camden has subsided, but two similar cases are reported from Bridgeton and Millville, N. J. According to a recently issued statement of the New Jersey State Board of Health, Trenton enjoys the distinction of having had no case of smallpox during the year ending October 31, although there were 225 in the rest of the State. Health officers visited Ottawa University on Monday, and after an investigation ordered the college placed under quarantine. Three cases of smallpox had developed in the institution since Saturday, and all the victims have been isolated on Porter's Island. In Brooklyn five cases of smallpox were recently discovered in an apartment house on Eighth Avenue, and the Health Board is considering the bringing of an action against two physicians who neglected to report the cases. In Orange, N. J., the health authorities have been struggling for a long time to erect an isolation hospital for smallpox cases, but have only just succeeded. A year ago they built a hospital, but the frightened citizens burned and wrecked the building before it could be occupied. One night a week ago they again put up a wooden building at night, and before morning it was occupied by four patients.

Opening of the Building of the Morris Plains Hospital.—The official opening of the new annex building of the Morris Plains New Jersey State Hospital took place on Thursday, November 21. After an address by the Rev. Dr. J. M. Buckley in the chapel of the main building, the guests walked through the tunnel to the annex where a reception was held in the hall, on the top floor. The address of welcome was by Mr. Patrick Farrelly, President of the Board of Managers, who formally presented the new building to the State, and it was accepted by Governor Foster M. Vorhees in an address in which he thanked the business and medical departments and Board of Managers for the very efficient management and the excellent condition of the institution. Rev. Dr. Buckley of the Board of Managers then read a historical sketch of the Morris Plains and Trenton Institutions.

Dr. Henry M. Hurd of Johns Hopkins University then read an interesting paper regarding the insane and hospitals for their care. In the absence of Governor-elect Franklin B. Murphy, U. S. Senator Jas. Smith delivered a short address. The closing address was made by medical director Britton D. Evans. He spoke of the training school for nurses connected with the hospital, and related facts regarding the new and the main buildings, and then gave an address on "The advance made in the care and treatment of the insane." The exercises ended with benediction by the Rev. Father A. M. Eagan of Morris Plains.

The Western Surgical and Gynecological Association.—The eleventh annual meeting of this society will be held in Chicago on December 18 and 19, under the presidency of Dr. A. F. Jonas of Omaha. The sessions will be held in the Great Northern Hotel. A banquet will be given by the Chicago members of the association on the evening of the first day of the meeting.

Sir William MacCormac, whose death in December 4, at Bath, was announced in these columns last week, was born in Belfast, in 1830. He was made a member in 1857, and a Fellow in 1871, of the Royal College of Surgeons of London, and a fellow of the Royal College of Surgeons in Ireland in 1864. He practised first in his native town, being for several years surgeon to the Belfast Royal Hospital. He later went to London, where he made his great reputation. He was for many years lecturer on surgery, and Attending Surgeon at St. Thomas Hospital, and later was consulting surgeon to this and several other London hospitals. He was made a knight in 1881, and a baronet in 1897. He had considerable experience in military surgery, having been surgeon-in-chief of the Anglo-American Ambulance in the Franco-German war, and also seeing service in the Turco-Russian war. At the outbreak of hostilities in South Africa, he was sent to the field as chief civil consulting surgeon. He was an honorary member of a number of foreign medical societies, and was the recipient of decorations from many of the sovereigns in Europe.

Insanity and Divorce.—A study of Prussian vital statistics recently published seems to show a relation of some sort between divorce and insanity and suicide. Out of a million persons, 348 divorced women committed suicide as compared with 61 married women. Three hundred and eighty-six married men committed suicide as compared with 2,834 divorced ones. In the insane asylums in Würtemberg a similar study shows 3,024 persons who had been divorced as compared with 283 married persons, 460 bachelors and maids, and 672 widows and widowers.

Obituary Notes.—Dr. James E. Gibbons of Baltimore died suddenly of cardiac disease on December 2. He was born fifty-eight years ago and was graduated from the Washington University School of Medicine, now merged into the College of Physicians and Surgeons of Baltimore, in 1868. A widow and one son, a practising physician, survive him.

Dr. Charles H. G. Steinsieck of this city died on December 3. He was a graduate of the New York University Medical School in the class of 1882.

Dr. John E. Beers of Danby, N. Y., died of apoplexy on December 4 at the age of sixty-one years. He was a graduate of the Medical Department of the University of Georgetown, D. C., in the class of 1864.

Dr. David McDill, Surgeon in the United States Penitentiary at Fort Leavenworth, Kansas, died of apoplexy on December 4 at the age of forty-one years. He was a graduate of Rush Medical College, Chicago, in the class of 1887.

Dr. Isaac Newton Evans of Hatboro, Penn., died suddenly of cardiac disease, on December 3, at the age of seventy-four years. He was born in Chester County, Penn., and was graduated in arts from Bowdoin College, and in medicine from the University of Pennsylvania. He served three terms in Congress as a member from the Seventh District of Pennsylvania.

Dr. Charles J. Essig, a dental surgeon, died of pneumonia on December 2, at his home in Wallingford, near Philadelphia. He was a graduate of the Jefferson Medical College in 1876. He was editor of the "American Textbook of Prosthetic Dentistry," and was Dean of the Dental Department of the University of Pennsylvania.

Dr. F. Semeleder of Orizaba, Mexico, died there recently. He was an Austrian by birth, and came to Mexico as the personal physician of the ill-fated Maximilian. After the latter's capture and execution, Dr. Semeleder remained in the country and built up an extensive practice.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ANNUAL MEETING OF COLLEGE OF SURGEONS—THE COMING ELECTION—ULCERATION OF OESOPHAGUS AND STOMACH FROM SWALLOWING ACID—HOME OFFICE REPORT ON INEBRIATE REFORMATORIES—WOODHEAD ON MORPHINE AND ALCOHOL—ARCHDALL REID ON ALCOHOLISM IN SMALLPOX—VACCINATION—A STUDENT'S HALL—RECENT DEATHS.

LONDON, November 22, 1901.

YESTERDAY afternoon, the annual meeting of Fellows and Members of the Royal College of Surgeons was held. The President (Mr. Howse) took the chair at the semi-solemn comedy, and in noticing the report of the year which ended July 31, drew special attention to the fact that for the first time the names of members who had died during the year had been inserted. Very proud must members be that they are thus thought worthy to rank with Fellows after death.

A motion was carried adhering to the resolution regularly passed for the last seventeen years in favor of members being represented on the council of the college, and asking that body, which has hitherto refused, to suggest an alternative scheme for giving members a share in the management of their college and their own property.

Another resolution was carried regretting the action of the council in contravening the regulations of the general medical council.

A motion was also carried in favor of the representative of the college in the general council, being elected by the fellows and by members of ten years' standing, though why ten years of practice should make a man a better judge of candidates does not appear.

A motion in favor of making these meetings open to the public was lost by eight votes against seven.

A further proposal was moved and seconded, asking the council to support a bill for amending the medical acts. This was dropped on the President promising to bring the subject before the council.

So passed the seventeenth meeting of this series with about as much prospect of effecting a reform as its predecessors. We ought to be thankful to the few reformers who take the trouble to keep these matters alive.

The approach of the election to the general medical council is causing a slight degree of interest—stimulated by speeches of candidates and other electioneering tactics. It seems doubtful, however, whether the prevailing apathy can be aroused enough to increase the poll. So little is hoped for from the council with its solid phalanx of corporation interests. What can three representative members do, especially when they are not agreed, as has often happened? One indeed actually taunted another that he could not find a seconder to one of his reform resolutions. If he could not agree with it, he might have seconded it *pro forma*, as he must have known that many hundreds of electors approved of it.

Another curious development is a sort of joint candidature and mutual testimonializing.

One candidate pleaded for another that his speeches would be listened to by the President—thus insinuating that his opponent's would not. This seems a slur on the president's impartiality. Besides we do not want long speeches. Thirty years' talk has done us no good.

Another way in which time and a certain sort of eloquence have been wasted is the proposal of changes which are quite outside practical reforms. Thus it has been proposed to divide England into three districts—one member to be elected for each—as if professional interests differed according to localities, or representatives should be selected according to their residences. The proposer of this scheme ought to have known that one object of establishing the council was to abolish territorial distinctions—an object which has been accomplished so far as to substitute one pharmacopœia for the three which formerly oppressed us. Why set up new topographical distinctions?

Two candidates are on the council of the British Medical Association, and seem anxious to remit some questions to that body. But we have no proof yet that its reorganization has reformed it, and, of course, it has not the standing of the general medical council.

A Scotch candidate says his "opinions are at one with the English candidates'" on the midwives' question. Perhaps, he means that as a joke, for the English candidates are not at one with themselves on the matter. One of them who formerly condemned registering the "camps" has been captured by the registrationists.

Ulceration of the œsophagus and stomach from corrosive acid poisoning was the subject of a paper read by Mr. Keetley at the Medico-Chirurgical Society. He related three cases due to swallowing strong hydrochloric acid, and offered as a conclusion that surgical intervention should be almost immediate, as it would be a mistake to postpone it until the patient would be dying from inanition. He thought the patient should receive neither solids nor liquids by the mouth for several weeks; so he would not allow oral feeding as soon as the patient could swallow without pain, but wait until there was good reason to believe that healing was complete. When the injuries are serious, as they mostly are, he held that the sooner the operation is performed the better. Of course, we can only conjecture whether healing has taken place; in one of his cases, the mouth and lips healed in eighteen days, but active ulceration of the gullet was found at the post-mortem on the eighty-fourth day. As to the operation, he was inclined to a gastrostomy combined with a gastro-enterostomy, and carrying the tube some distance down the efferent loop of the jejunum. To provide for washing out and draining the stomach, he suggested a double tube, the shorter canal opening into the stomach. This could be managed by passing a long narrow gastro-jejunal tube through a wide, short gastric tube. As soon as the patient could swallow without pain, he would give hot water or hot saline solution *ad libitum*, allowing it to escape by the short tube so as to wash out in some degree the stomach.

In the discussion on the paper, surgeons questioned the propriety of withholding food so long, and seemed inclined to support the old plan of allowing it as soon as it could be swallowed without pain. It was also remarked that a fair-sized bougie could often be passed with ease when swallowing gave pain, showing it to be due to spasm.

The Home Office has just issued the second annual report of the certified reformatories established under the Inebriates Acts of 1898–99. There were five such institutions last year—an increase of one. From the commencement of the work until the end of last year 232 inebriates were sentenced and sent to these reformatories. There are in addition to these twenty-two licensed retreats with accommodations for 357 patients, who enter voluntarily, signing to stay for a definite period. Last year 219 such "signed patients" were admitted, 175 discharged, and 131 left on the expiration of the time signed for.

Professor Sims Woodhead, in a recent lecture, gave an emphatic warning against taking alcohol after morphine. He called it "absolute folly—one of the worst things a man can do." It is almost impossible to cure a person who takes both. In delirium tremens it was once customary to give alcohol—now it is at once cut off altogether. It is held by some that in pneumonia there is sometimes a short period when the heart is very irritable, and alcohol may be used to dull it; "it is just possible it may be of some use then, but the doctors who prescribe it in these cases have a definite reason for doing so. It is only a temporary measure, and the damage it does may not be so great as the irritation it checks." Dr. Woodhead added that this is the only case in which alcohol may be given; in accidents he held it to be bad practice to give it to deaden pain, and he "would not dream of giving it when there is danger of blood-poisoning."

Dr. Archdall Reid has just published a 6s. book on "Alcoholism: A Study in Heredity," which is largely made up of some of his interesting, if unconvincing, contributions to journals. To some extent the book may be regarded as a sequel to his previous works on evolution and on immunity. He does not anticipate that his data or his conclusions will go unchallenged; but that does not deter him from stating them with dogmatic assurance. He holds (1) That characters acquired by the parent are not inherited; (2) That evolution results from the *stringent* elimination of the unfit; (3) That when the elimination which has caused the evolution of any character ceases, or nearly ceases, that character undergoes degeneration; (4) That degeneration is due to atavism—to a process of reversion which, step by step, retraces the previous evolution, till if it be continued long enough, that more or less remote ancestor is approximated to in whom the character did not exist.

Following up these assumptions, he says that people only drink alcoholic liquids for three reasons: (*a*) To satisfy thirst, (*b*) To gratify taste; (*c*) To produce an effect on the brain. Only the last is the cause of drunkenness, and so alcohol becomes a selective agency picking out those who are cursed with the "alcoholic diathesis," which assumed state or predisposition he further declares to be "certainly inborn, and therefore as certainly transmissible to offspring." Any one who is so enamored of these beautiful words evolution and immunity as to accept these views without hesitation may perhaps not demur to the corollary offered that all previous attempts at reform have failed because they contend against Nature. Dr. Reid proposes to copy Nature by eliminating the drunkard. How? Simply by forbidding the drunkard to pro-

create children under a penalty of a month's imprisonment!" Can he be serious?

Smallpox still progresses. On Monday, the number of cases under treatment passed the fourth hundred, and yesterday reached 442.

A good deal of dissatisfaction is being expressed with the local government board on account of its restricting the supply of its lymph to public vaccinators. At a time when every one is anxious to be revaccinated, and when immense numbers prefer to be operated on by their own attendants, it is especially desirable that lymph should be easily obtainable, and beyond reproach as to its purity and efficacy. The lymph prepared by the board is produced at the public expense. Why should not the public be allowed to profit by it? There are a number of private establishments which are prepared to meet the demand, but they do not enjoy the full confidence of the people, and some of them have grievously disappointed their customers. Consequently, there is much grumbling about the restriction of the government supply, and instances of the inactivity of some private supplies have been published.

The public vaccinators are better paid than hundreds of doctors in the poor districts who are not only obliged to buy lymph, but are prevented from using that of the government board.

Liverpool is indebted to Sir A. L. Jones, K.C.M.G., the founder of the School of Tropical Medicine, for another institution—a residential hall for students.

Dr. Henry Sutherland died on Tuesday, aged fifty-nine years. He was a graduate in both arts and medicine of Oxford, and for many years lecturer on insanity at the Westminster Hospital. He had been a resident at Wakefield Asylum, and contributed to its report 1877 his Borderland cases. He also wrote in the Dictionary of Psychological Medicine and other journals important articles on his specialty.

Surgeon-General Manley, C.B., V.C., died on the 10th. In the course of his distinguished career he served in the Crimea; in New Zealand, where he won the V.C.; in the Afghan War, 1878, and the first Egyptian Campaign. He was with the British ambulance in the Franco-German War, and was awarded the Iron Cross for "devoted and excellent conduct in seeking out and caring for the wounded."

Sir James Agnew, Ex-Premier of Hobart, whose death on the eighth is announced, was a medical man and practised many years in Hobart. He took his M.R.C.S., Eng., in 1838, and M.D., Glasgow, 1839. Soon afterward he went to Tasmania, where he achieved the highest honors the colony could confer.

Dr. Stopford Taylor died on the 11th inst. in his eightieth year. He was formerly M.O.H. for Liverpool, an office he only resigned about seven years ago.

Mr. A. H. Smee, who died on the 8th inst., was the son of the late Alfred Smee, Surgeon to the Bank of England, and author of "My Garden." The son took the M.R.C.S., Eng., in 1866, and for some time devoted himself to scientific research. Later, he became attached to a life insurance company, and only last month there was published his "Tables and Diagrams Illustrating Comparative Rates of Mortality."

James William Jeans, J.P., of Granthan passed away in his eighty-eighth year on the 12th inst. He took his M.R.C.S. in 1836. Another octogenarian, Dr. Horrocks, died on the 15th, aged eighty-five.

John Palmer Way, formerly Surgeon to the Portsmouth Hospital, died in that town, where he had practised since 1867. He was born in 1838, and died on the 16th inst. of angina pectoris, deeply regretted by his professional brethren.

THE PROBABILITIES OF THE ACTION OF THE X-RAY IN CANCER.

To the Editor of the Medical Record

This problem recently propounded to the medical profession is of transcendent interest to the sufferer from inoperable cancer, and of an almost equal interest to the worker in the fascinating field of the Rontgen ray. Two factors confront each other—the cancer tissue and process, and the ray of Rontgen, both of them yet to issue from the cloudlands of uncertainty as to their exact nature. True, reams of literature representing untold hours of human effort to solve the two problems exist; true, also, that the already ascertained facts constitute, so far as they go, triumphs of science, and yet the bald fact remains that a final answer as to the nature of each is yet to be granted to us. For this reason the evidence as to the curative effects of the *x*-ray in cancer must at present be of an experimental and clinical nature. Are there *prima facie* reasons why the *x*-ray should set up tissue changes in any tissue and as a consequence in cancer tissue? There certainly are.

There is, first, the well-known *x*-ray burn—a possibly profound necrosis of tissue of every tissue. This effect may be produced at will and to a degree and within limits desired by a skilled operator. To produce it is no matter of accident at all if one takes into account the state of the tissue treated—namely, whether debilitated or sound—the nature of the *x*-ray employed—namely, whether more or less highly penetrating—the distance of the source of the ray from the tissue, etc., etc. But to quote this effect is merely to do so in order to point out the actual power of the *x*-ray for harm and at the same time to point out that in this respect it resembles most other effective remedies in surgery or medicine—like powerful poisons and cutting instruments, for instance—for such may be used in degree and manner to do harm or to do good.

So with the *x*-ray.

Now, the good that the *x*-ray may do is a chapter in the story which is being worked upon by many observers throughout the world.

And its influence for good and for the healing of tissue is a positive fact which I have verified time and time again in practice. From the days when Mr. Edison first proposed the *x*-ray treatment for blindness (atrophy of the optic nerve cases), many have worked upon the problem of applying the *x*-ray in the treatment of diseases. But an atrophy was an unfortunate branch of the subject to begin upon, and naturally little or nothing came of the effort. Far more brilliant and less problematical are the effects derivable from the impact of the *x*-ray upon tissue, if we turn to tissues which are not atrophic and to a ray which is not too destructive—namely, to a ray which is stimulating and to a tissue in which a reaction to normal nutrition may be set up as a strict consequence of the stimulation ("irritation"). A fair parallel to such action of the ray and the tissue is found in ordinary sunburn. The dermis appears to be similarly affected in each case. And could we lead the sun ray to the interior and remotest interstices of the tissue, we might perhaps do with the sun ray what is possible with the *x*-ray. But unfortunately the sun ray is stopped in its course at the surface of bodies. On the contrary, the *x*-ray penetrates bodies. But our parallel teaches that if the *x*-ray excites and stimulates the skin, so too, inevitably and logically, it must produce the same effect upon deeper tissues. That it does this we know. Therefore it seems to me that there can be no doubt that all the probabilities favor the deeper action within the tissue of cancer, lupus, etc., claimed. But granting the deeper action of the *x*-ray, and we must grant it, it yet remains to be seen if this especial action is one which restores a cancer tissue to a normal tissue. I do not believe, from the evidence now before me in cases now under observation, that we can afford to ignore the new hope and the new facts lately presented.

William J. Morton, M.D.
10 East Twenty-eighth Street

LETTER FROM THE FALKLAND ISLANDS.

(From Our Special Correspondent.)

Stanley, Falkland Islands, October 24, 1901.

The health of this colony is all that can be desired, there being an entire absence of epidemic and endemic disease—notwithstanding the most imperfect drainage, if, indeed, drainage it can be called, everything being allowed to look after itself, the safeguard being the strong prevailing winds. This is demonstrative proof that nature is most beneficent in these storm-beaten islands.

During the past year, two American ships, being in distress, put into Stanley Harbor. The *Henry Failing*, commanded by Capt. Mathews, and the *Blanchard*, Capt. Courtney, the former had several men suffering from gangrene, the result of frostbite; they were colored men. I amputated the right hand of one man, named Edwards, a native of the Mantibos, with success. Two days afterward, the left hand, which I tried to save, showed such evident signs of gangrene extending, that I was constrained to perform a similar operation, but I regret to say that under the influence of chloroform the man died, although I had immediate recourse to artificial respiration and other restoratives. This is the first death by chloroform I have had in my practice, extending over a period of thirty-five years. I had several minor operations on the men of both ships, in removing the phalanges, etc. A seaman named Erichsen, of the ship *Blanchard*, sustained a transverse fracture of the right patella, by muscular contraction of the quadriceps extensor muscles in trying to save himself from falling backward, six weeks previous to my seeing him. I

approximated the fragments, using much force to overcome the action of the above-named muscles, then used the emplastrum ferri in strips, over one inch in width, in figure of eight, and a stiff bandage over all. The man proved a refractory patient, and would insist on walking about, but he made a marvelous recovery, the line of union between the upper and lower fragments being as fine as a hair. He was sent by Consul Rowan to the United States.

Four months ago a local shopkeeper met with a similar accident, the upper fragment in this case was four inches apart from the lower. In addition to the treatment pursued in the above-mentioned case, I placed a splint on the outside of the limb and enjoined the recumbent position, with the heel well elevated. This patient has for many years been a martyr to podagra; he is now attending his business and has considerable mobility of the joint. Of course, I have not looked for osseous union, but the ligamentous union has been satisfactory. On the 25th of March, a police constable, while stepping over a drain, in some unaccountable manner sustained a compound-comminuted fracture of the right leg; the tibia was splintered for three inches above the internal malleus, both tibia and fibula protruding through the separate openings. My first idea was amputation, my second to try conservative surgery. I reduced both bones, removing splinters and spicule, using the usual disinfectants, and applying three splints; one on the outer side from the knee, extending beyond the foot; another on the inner side, and the third from the popliteal space to the heel, with fracture pads and medicated wool. Every second day I dressed the wounds. On the fourth day, symptoms of gangrene supervened, which caused me anxiety, more especially as a greenish slough was at the bottom of the openings. Fortunately, these alarming symptoms passed away. The man made a rapid recovery, and now attends his duty as police officer; of course, there is slight shortening of the leg, which is obviated by a high heel, and a certain amount of stiffness in the gastrocneme muscle, which is gradually wearing off.

In November, 1899, a man named C—— contracted a virulent form of syphilis from his wife, a woman of well-known loose character. It was a phagoclinic ulceration, the penis was swollen to an enormous size, and covered with confluent chancres; the foreskin and integument had sloughed off, leaving the corona glandis exposed, the corpora cavernosa and spongiosum penis were covered with sores. I adopted topical measures at once, but a considerable portion of the penis dropped off; the bichloride of mercury and bulk were freely given. Two months after the man went to work. September 12, 1901, I was again called to see this man; he was suffering from condylomatis and orchitis of the left testicle, which was swollen as large as a small goose egg. The patient was recovering when his evil star was again in the ascendant, as from the same source he is now prostrate with gonorrhœa. The lady in question reminds one of the celebrated opera dancer at Lisbon (mentioned by Cooper), as her poison, like that of the serpent, hurts not herself.

DR. FRALICK'S DISCOVERIES.

To the Editor of the Medical Record

Sir: The Medical Board of the Metropolitan Hospital, Department of Charities, Blackwell's Island, disavows any connection with the alleged discoveries of Dr. Wilfrel Fralick in regard to the treatment of Tuberculosis and other diseases, and is in no way responsible for the publicity of the same. By order of the Medical Board.

Arthur T. Hills, M.D., Secretary.

His Recompense.—A popular physician was much pleased with a certain aerated water, and by his assiduous recommendation procured for it a celebrity it justly deserved. The doctor acted solely in the interests of humanity generally, and expected no return.

To his surprise there came one morning an effusive letter from the company, stating that his recommendations had done them so much good that they "had ventured to send him a hundred —" Here the page came to an end.

"This will never do," said the doctor.

"It is very kind, but I couldn't think of accepting anything."

Here he turned the page, and found the sentence ran: "Of our circulars for distribution."

Progress of Medical Science.

The Boston Medical and Surgical Journal, December 5, 1901.

Prostatic Calculus Removed Through Perineal Section.—Charles G. Levison reports a case of this rare affection, which was not recognized until an examination was made by the rectum, which revealed an enlarged prostate with indurated lobes. The right lobe was the size of a pigeon's egg. A so-called middle lobe could be palpated; this had a smooth surface, and produced the impression as if a stone lay imbedded in the prostatic substance. The author describes the operation by means of which the stone was removed. It weighed about six grams, and should be classed as an essential calculus.

The Scope of Vaginal Section in the Treatment of Pus in the Pelvis.—Edward Reynolds reports eighty-two abdominal sections without mortality, and eighteen vaginal sections with one death due to accidental causes. He considers that there are four advantages from the vaginal route, viz., diminished risk of peritoneal infection, the possibility of maintaining excellent drainage, the rare sequence of hernia, and the almost total absence of post-operative shock. Convalescence is usually short. It seems quite possible that vaginal sections, in selected cases, may leave the patient with pelvic organs capable of normal functions; and, if this be true, it should have precedence over the radical operation, which is, after all, always available, after the failure of the vaginal operation to secure an absolute result.

The Similarity of the Early Symptoms of Simple Abdominal Contusion and One Accompanied by Severe Intestinal Injury; the Need of Explorative Cœliotomy as an Early Routine Measure.—John J. Bottomley says that at present we have no certain means of distinguishing between these two forms of injury. Pain, vomiting, shock, muscular spasm, distension, tenderness, external signs, and dulness are of little diagnostic value, as they may be alike in both cases. Neither does the pulse nor temperature give sure indications. An exploratory incision is the only certain means of ascertaining the conditions. This, to be of most avail, must be done within three to five hours after the injury. Exploratory laparotomy, combining, as it does, opportunity for a certain diagnosis and the best possible treatment, if severe injury be present, should be a very early routine measure in all but the most trivial cases of contusion of the abdomen.

Journal of the American Medical Association, Dec. 7, 1901.

Fear as an Element of Nervous Diseases and Its Treatment.—J. Punton says that morbid fear may sometimes proceed from within and be of purely psychic origin, in which case the external evidence is greatly modified and subdued, but the internal emotion is attended with marked mental dread or fear, amounting to almost despair. In such cases the attention and imagination enormously augment its intensity and at times torture the patient to such a degree that he loses control of himself and becomes almost mentally alienated during the paroxysms. Moreover, the emotion of fear under certain conditions proves stimulating, so that the frightened subject under its action seems to take on new strength and perform feats that would otherwise have been impossible without the unusual stimulus attending it. On the other hand, fear more often entirely overcomes the inhibitory power and renders the will powerless, so that all the vital functions are temporarily checked or held in abeyance. The emotion of fear may, therefore, be stimulating, inhibitory, or paralyzing to the vital functions according as the stimulus is strong or weak, and the reaction active or indifferent. Measures that are directed toward the relief of the physical conditions associated with morbid fear pertain largely to the removal of the cause. If the general health is depressed or found suffering from any toxic condition, such as lithæmia, auto-infection, and similar states, the use of the salicylates, alkalies, and saline cathartics, with proper diet, is often attended with marked relief. In the practical therapeutic realm of neurology and psychiatry, no symptom at times offers more obstinate resistance to all kinds of treatment than morbid fear; but in the majority of cases, if the principles referred to are intelligently, persistently, and scientifically applied, much can be done toward its permanent alleviation.

Temporary Clearing of a Cataractous Lens.—H. Woods reports a case of this nature, his patient being a woman of seventy-two years, who had been near-sighted all her life and was wearing — 9 D. for near, with occasional use of —10 D. for distance. The latter gave about 4/200 in each eye. The patient was a literary worker and had all her life subjected her eyes to constant strain. When examined, the fundus of each eye showed large but old and limited choroidal atrophies, mostly in the neighborhood of the papilla; the foveal region was good. The left lens

showed an axial nuclear opacity, rather a central deep cloud than spoke-like striations. In the lower and external periphery of both right and left lenses there were opaque streaks. Over two years passed before the second examination. A central deep cloud in the right lens was the only change observable. A year later, distant vision was the same as three years previous. The left eye had lost near vision from 1 to 6 Jaeger. The central haze noticed in the right lens a year before, and the opacities of the left lens seen at the first examination, were unchanged. So was the fundus in each eye. The patient was seen again about eighteen months later, when full homatropine dilatation revealed a thin rim of red reflex at the equator. The rest of the lens had lost its transparency. Its color was reddish-yellow or amber, much darker than is ordinarily observed. No sector reflex was obtainable by oblique illumination, nor iridic shadow. Six months later the patient stated that for some time she had been seeing better with the left eye, and counted fingers at four feet. Ophthalmoscopic examination showed the fundus clearly. The axial opacity seen in the beginning and the inferior external striations on the equator were unchanged, but between the central cloud and equator the lens substance was transparent. Under homatropine a careful examination was made of the fundus. A small extravasation was found a little to the foveal side of the papilla, and below the horizontal meridian. This was subretinal. The vitreous showed a number of small muscæ. The latter and the extravasation were new. It seemed reasonably clear that an acute choroiditis had ensued; that the reddish-yellow lens opacity was secondary to it, and that this opacity had cleared with recovery of the choroiditis. The right eye had not changed.

The Rôle of the Endothelium in Inflammation.—E. R. Le Count says that the ability of endothelium to form connective tissue, or the active participation in cicatrization of the endothelium of certain regions, are questions that have formed the basis of many researches and many polemics. Without doubt, the older belief that this capacity was inherent in all varieties of endothelium owed its general acceptance, in a measure, to the accounts published fifteen to twenty-five years ago dealing with the organization of thrombi. That the endothelium of blood vessels should possess such a property perhaps met with the more ready welcome, since it was so thoroughly in accord with the prevailing ideas as to the genesis of the cells. With the entrance of controversies as to the origin of the endothelium of certain situations among the embryologists, it is but natural that the endothelial or epithelial nature of certain of the cells in question should be reflected by pathologic problems. So far, the endeavor has been to separate the endothelium of serous membranes from other forms, and it is with these cells that contrary opinions have been agitated. The prolonged interest in these questions is largely to be attributed to ignorance of the exact methods by which fibers are formed normally; with the definite proof of the secretion theory or of their direct production by fibrillation of cells, or of the conditions under which either of these processes occur, will come a seasonable time for investigations to determine how this or that group of cells may share in the development of pathologic fibrous tissue. It is generally accepted that endothelial cells may assume certain embryonal properties in inflammation and assist in the formation of granulation tissue, but there the trail is lost; differences between embryonal cells of diverse geneses as they occur in this tissue are not sufficiently marked that the subsequent behavior of separate forms is readily traced. Although there is no consensus of opinion as to the rôle endothelium plays in the growth of cicatrices, yet some recent works point strongly to the necessity of divorcing the lining of the pleuro-peritoneal cavity from other forms of endothelium, at least so far as some of its qualities are concerned. Certain observers who concluded from experiments that the endothelium of serous membranes was directly concerned in the production of organized adhesions have recently moderated their statements as to such an eventuality. When masses of fibrin in fibrinous exudates are replaced by connective tissue, the organization always proceeds from the point of their anchorage, and this is true in spite of the fact that such masses may have been completely covered over by newly produced endothelial cells from the edges. Thus gradually and from various sources, as before stated, an agreement has been reached that the lining of the serous cavities—pleura, peritoneum, pericardium, and tunica vaginalis—is clearly allied to epithelium.

Etiology of Pericarditis.—R. A. Preble presents the following conclusions: (1) Cases of clinically primary acute pericarditis occur, but are rare. (2) Diseases to which pericarditis appears as a complication are in order of their frequency; pneumonia, 34 per cent.; rheumatism, 28.36 per cent.; chronic diffuse nephritis, 11.2 per cent.; tuberculosis, 10 per cent.; sepsis, 4.7 per cent.; aneurysm, 2.6 per cent.; typhoid, 1.7 per cent. (3) The more extensive a pneumonia the greater the danger of this complication. (4) The danger is somewhat greater with left than with right-sided pneumonia. (5) When only one lobe is involved, the danger is least with a right upper-lobed pneumonia, and greatest with a right middle or left upper-lobed pneumonia. (6) With a unilobar pneumonia the chances of a pericarditis are 1 in 40; with a bilobar or trilobar, 1 in 10; with a quadrilobar, 1 in 5, and with a pneumonia of the entire left lung, 1 in 8. (7) The mortality of pneumonia with pericarditis is 92.4 per cent. (8) Rheumatic pericarditis is complicated by endocarditis in 60 per cent. of the cases, *i. e.* three to four times the normal rate of cases of endocarditis. (9) The danger of pericarditis complicating rheumatism is the greater the younger the individual, and is somewhat greater with males than with females. (10) So far as acute pericarditis is concerned, the site and extent of the endocarditis is apparently of no importance. (11) Pericarditis appears as a complication of all forms of nephritis, but particularly the chronic diffuse nephritis with contraction. (12) It is an extremely ominous thing, for 22, *i. e.* 84.6 per cent., of the cases died. (13) It is still uncertain whether the pericarditis is toxic or infectious. (14) Tuberculosis excites only one tenth of the cases, and when one considers the extreme frequency of tuberculosis, pericarditis must be regarded as a rare complication. (15) Pericarditis may be a part of a generalized acute tuberculosis, but is more often the result of a chronic tuberculosis of the lungs or mediastinal glands. (16) Septicæmia and pyæmia contribute a very considerable number of cases of pericarditis. The primary focus may be remote or close to the pericardium. (17) Aneurysm of the aorta causes 2.6 per cent. of all the cases, a very high figure when one recalls the comparative infrequency of aneurysm. (18) Typhoid fever, which is rarely complicated by inflammation of the serous membranes other than the peritoneum, contributed 4 cases, which is 1.7 per cent. (19) The cases of obliteration of the pericardium are due to the following causes arranged in order of importance: Endocarditis, tuberculosis, chronic nephritis, aneurysm. (20) More than one-half of the cases in which the cause was clear, were due to endocarditis, or rather to some cause common to both the endocarditis and the pericarditis, and more than one-half of these cases showed a combined aortic and mitral endocarditis. (21) Relatively six times as many cases of obliteration of the pericardium occur with aortic and mitral endocarditis than with either lesion singly. (22) Tuberculosis causes but few cases of obliterative pericarditis. (23) Pericarditis, accompanying nephritis, is not always fatal, but may apparently end in the formation of adhesions.

New York Medical Journal, December 7, 1901.

On a New Principle in Nephropexy.—Carl Beck describes a method of operating which consists in the suspension of the kidney, after it is button-holed on the fibers of the nearest muscle. He gives the following account of a recent case: In a woman of twenty-four years the right movable kidney, after being exposed by a lumbar incision, was perforated near its lower pole by a trocar of a moderately large size, a procedure which caused but little hemorrhage. The margin of the spinalis dorsi muscle was incised then, and a bunch of fibers, just large enough to pass the renal buttonhole, mobilized. By a Péan forceps this band-like muscular flap was drawn through the renal hole made by the trocar. Then the end of the flap was fastened somewhat below its former muscular bed by iodoform silk sutures. Thus the kidney was held *in situ* only by living tissue. There was no reaction, and the operation seemed to be a success.

Ulceromembranous Angina Associated with the Fusiform Bacillus (Vincent).—J. Sobel and C. Herrman have made a careful study of the cases coming under their notice. They briefly review the literature of the subject, finding scarcely any reference to the disease by American writers. The term "chancroidal," perhaps better than any other, describes the condition. The patches on the tonsils seem to have a worm-eaten floor, the edge being on a level with or slightly above the surface. Except for a necrotic base, it looks like a punched-out ulcer. Depth varies from one-eighth to one-half an inch. All their cases had fever. With two exceptions the submaxillary glands were enlarged. Diagnosis calls for the differentiation from diphtheria, confluent lacunar tonsillitis, and other tonsillar inflammations. From diphtheria, it is distinguished by the facts that it is an ulcerative, not a membranous, process; does not tend to spread beyond the tonsil; presents no asthenia, and very few constitutional symptoms. From confluent tonsillitis, it is distinguished by the absence or mildness of constitutiona

symptom by the fact that is is a deep and not a superficial lesion, and by the fact that only tonsil may be involved. The bacillus characteristic of the affection is that described by Vincent and known by his name. The germ appears under two forms, those of fusiform bacilli and spirilla. The bacillus is about twice as long as the Klebs-Loeffler, some being bent to form a crescent, one arranged end to end in a wavy fashion, and at other times at an acute angle. Some are paired, while other are scattered in a field without any particular arrangement. They are always longer and thicker than the diphtheria bacilli. The spirilla are long and corkscrew-like with wide curves. The following points make the specific character of the germ highly probable: (1) Uniform presence in very large numbers, or at times in pure culture. (2) Gradual disappearance during healing, and rapid disappearance as the ulceration heals completely. (3) Presence of so few other germs, and (4) The fact that the malady may be transferred from one patient to an other

Medical News, December 7, 1901

Some Unusual Localization of Tuberculosis.—Frederick A. Baldwin reports several unusual cases. Tuberculosis of the hypophysis; tuberculosis of the intercostal tissue near the sternum, with secondary tuberculosis of the axillary lymph glands, primary tuberculosis of the Fallopian tube, with a large tuberculous abscess in the ovary, tuberculosis of the thyroid gland; tuberculosis of the uvula, adenomatous polyp of the cervix uteri showing tuberculosis.

A Case of Suture of a Stab-Wound of the Heart.—George Tully Vaughan reports a case and concludes from a study of the literature that: (1) The time has arrived when a wound of the heart should be operated on with as little hesitation as a wound of the brain, with the expectation under corresponding conditions of getting equally good results. The mortality must inevitably be high—not from the operation, but from the injury, especially if all cases, including desperate ones, be undertaken. Selection of cases in which the patient has survived five or more hours after receiving the wound would give a good percentage of recoveries, but such a selection is not to be recommended. (2) In all cases of wounds in the region of the heart, with symptoms threatening life, an exploratory operation should be undertaken by making an osteoplastic flap, by dividing the fourth and fifth costal cartilages at their attachments to the sternum and the ribs, about one inch external to their attachment to the cartilage, somewhat according to the method of Roberts. This flap, turned upas a door on a hinge, gives a good view of the pericardium, and the opening can easily be enlarged upward if more room is required. (3) While early and speedy operation is often essential to success, yet the importance of asepsis cannot be too strongly emphasized on account of the great danger of pericarditis and empyema. If there has been much hemorrhage a quantity of physiological salt solution, approximately equal in amount to the blood lost, should be injected into a vein, while the surgeon is operating on the heart, if it has not been done sooner.

Philadelphia Medical Journal, December 7, 1901.

Hypodermoclysis in Pediatric Practice.—W. C. Holloppeter sums up the chief fields of usefulness of this treatment as follows: Hemorrhage in the new-born, from the genital or umbilical cord; in purpura, in cases of general wasting from intestinal disorders; and especially the toxæmias, associated with the acute eruptive fevers, and diphtheria. In syphilis and in tuberculosis it aids very materially the other therapeutic measures. The writer's technique is as follows. In afebrile cases, such as are found in general atrophy or wasting following the infectious diseases, the solution should have a temperature of at least 115° or 120°, and be delivered to the tissues at 106°. This temperature must be sustained throughout the operation. The injection may be made in very young children through a large hypodermic syringe, or, if a suitable apparatus is obtainable, by gravity. In young children, a convenient way of administering it is with the old-fashioned large antitoxin syringe, which holds one to two ounces. The point preferable for injection is near the great trochanter. It is often necessary to benumb the skin either by ice or by sulphuric ether.

Amyotrophic Lateral Sclerosis, with Report of a Case.—Thomas Luther Coley reports this case. His patient was a man aged forty one years. When about twelve years of age he had a fall, and, although he recovered from it, he always afterward had a sensation of stiffness in the lower spine muscles which greatly fatigued. In the fall of 1898, he suffered greatly from exposure to cold. His legs first became involved. There was no alteration of sensation save cramp-like seizures in the calves worse at night, and some sense of formication at times. The tactile, thermal, and pain senses were normal. Until December, 1899, the case presented a typical example of the symptom-complex called spinal spastic paraplegia. At this time the upper extremities became gradually involved. Atrophy developed and contractures of the hand appeared. The head became affected. About the first of March, bulbar symptoms appeared. The patient died suddenly in July, 1901. In the treatment of this affection, electrotherapy and massage seem to give some degree of comfort for a time. General tonic treatment is followed by indifferent results. The greatest benefit is derived from the use of salt-water baths early in the malady, and of the thermal cabinet later in the disease. The spasticity in the author's case was remarkably lessened for a few hours after these baths, but no permanent relief was afforded.

American Medicine, December 7, 1901.

Massage of the Stomach.—Mark I. Knapp concludes that from a subjective point of view, massage (at least after the methods of effleurage and tapotement used by the writer) was of benefit in the six cases which he reports. The patients felt so well that it was with difficulty that they were kept under treatment during the later period. This feeling of improvement, however, was mostly psychic, as shown not only by the actual chemical and physical determination of the gastric contents after each massage, but from the condition a few weeks after the cure. The writer adds that whatever good there is in massage, the stomach is not adapted for it.

Vaccine Production and Vaccination.—George G. Groff thinks a competent commission should be appointed to promulgate the proper methods of vaccine production, and the best methods of applying vaccine to human beings. This commission should investigate and report upon the following questions: (1) From what tissue or pathological product in the vaccinated animal should the virus be taken, and at what time after vaccination? (2) What is a typical vaccine vesicle, stating accurately the appearance on different days, and what is a typical vaccine scar? (3) How can we arrive at a positive diagnosis of the mild form of smallpox in which there are no deaths? The writer then gives a brief review of the variety of opinions held on these points. He adds that the epidemics which he has watched for thirteen years were always the result of the failure of physicians to diagnose the disease until it had spread throughout the community.

The Treatment of the Various Hemorrhages and of Shock.—Herbert L. Taylor speaks of the treatment of various forms of hemorrhage. In epistaxis, if the hemorrhage is severe, use tincture of veratrum viride or tincture of aconite in three to five drop doses, followed in fifteen to twenty minutes by a smaller dose if required. If bleeding does not cease, styptic measures may be used locally. Hemorrhage from a cut arm, finger, etc., should, if possible, be arrested by compression or ligature. Metrorrhagia, independent of menstruation, if produced by a polypus, or some one of the various causes of uterine disease, should be treated by oil of erigeron if there is oozing, and ergot if there is active bleeding, or extract of hamamelis and potassium bromide. Aconite should be given early in an attack of hemoptysis. Hemorrhage from the bowel is treated according to its point of origin. If in the small intestine, remedies must be given by mouth; if in the large, by rectum. Hæmaturia is treated according to its source. In shock, the treatment consists of $\frac{1}{30}$ grain atropin sulphate hypodermically, and external application of heat.

The Lancet, November 30, 1901.

Treatment of Whooping Cough.—E. Magennis reports two cases. The nares were irrigated with warm carbolic lotion (1 to 40 with a little glycerine added) through a small syringe with a soft-rubber nozzle. Six ounces of the solution were used in each nostril three times a day. The author thinks that the irrigation, by keeping the naso-pharynx disinfected, diminished the frequency of the paroxysms and cough, and greatly lessened the duration of the disease. He admits the possibility of some of the fluid getting into the Eustachian tube.

About Alkaptonuria.—A. E. Garrod believes that there is a very special liability of alkaptonuria to appear in the children of first cousins and gives data relative to certain families as bearing on this point. He believes that the facts he adduces lend support to the view that alkaptonuria is what may be described as a "freak" of metabolism, a chemical abnormality more or less analogous to extra-parental malformations. They can hardly be reconciled with the theory that it results from a special form of infection of the alimentary canal. There is here no question of the intensification of family tendencies by inbreeding, for in no instance were the parents

themselves alkaptonuric, and, as has been already mentioned, there is, up to now, no recorded instance of alkaptonuria in two generations of a family.

A Case of Lead Poisoning Causing Insanity.—The patient of W. S. Stalker was a plumber, thirty years old. He was taken acutely ill, and a diagnosis was first made of influenza, later of typhoid fever. After a while, delusions of persecution with hallucinations of sight and hearing came on, and later acute mania. There was marked paralysis of his extensor muscles of the forearms, and wrist-drop was very pronounced. He was unable to stand, and, when held in the upright position, his legs gave way under him, and he tended to drop in a sitting posture. There was very evident tremor, and this was most noticeable when he attempted any movement. There was no very marked increase in the knee-jerks, and ankle clonus was absent. Anæmia was very pronounced, and the face was wrinkled. On the gums there was an exceedingly well-defined blue line. On the use of bromide and iodide of potash, recovery supervened, though during treatment the patient had severe epileptiform seizures.

A Case of Myxasthenia with Remarks on Kindred Affections.—W. Overend reports the case, the patient being a woman of forty-two. She seemed to be suffering from an atrophy of the mucous or goblet-celled epithelium, a condition known as "myxasthenia." In this state there seems to be a desiccation in scattered areas throughout the mouth, and, in fact, through the entire alimentary canal. As a result, the normal supply of mucus is not forthcoming, and consequently there is irritation of nerve endings at various points to which the pains of the malady seem referable. Abnormal dryness of mucous membranes may occasionally be an accompaniment of the gouty and diabetic diatheses. The entire pathology of gout is not exhausted in the idea of uric acid, nor is that of diabetes altogether embodied in that of sugar, since we know that these two substances are merely the outward manifestations of a profound disturbance of metabolic activity, the elucidation of which is still reserved. The presence of mucin in abundance within the synovial fluid, where uric-acid deposits most frequently occur; the existence of a carbohydrate moiety in the mucin molecule, and the diminution of saliva and desiccated tongue of diabetic patients are suggestive facts which may lead to the discovery of interesting relationships.

Symptoms and Treatment of Movable Kidney.—Henry Morris presents the following conclusions: (1) When movable kidney is associated with enteroptosis, no operation should be performed on the kidney unless it is evident that the more serious symptoms are due to the mobile kidney alone, and not until after the trial of a well-fitting abdominal support and the careful dietetic and medicinal treatment of the gastric and intestinal disorders. Should these means fail, and the kidney evidently be most at fault, nephropexy, followed by the wearing of an abdominal belt, should be tried. (2) When a movable kidney is complicated by a movable liver, or when both kidneys move, the same rule should be followed as in general enteroptosis; in the case of both kidneys moving (when both organs have been giving trouble), they should be fixed one after the other at an interval of a week, so that convalescence from both operations may be taking place simultaneously. Morris has in several instances thus operated upon both organs with the most satisfactory results. (3) When the movable kidney occurs in a hysterical or neurasthenic patient, all palliative means should be tried before resorting to an operation, and the patient's friends should be informed of the uncertainty of the result from operation. The statistics show that a cure may be hoped for by nephropexy in about half of these cases. (4) For uncomplicated movable or floating kidney, in which the principal symptoms are pain and gastro-intestinal troubles, the operation may be confidently advised and carried out without any previous trial of belts or of rest. (5) When renal crises are a feature of the case, nephropexy ought to be strongly urged, because of the impossibility of keeping the kidney in its proper place by a belt, and because of the constant risk of hydronephrosis and recurring pain, even if the renal crises can be kept under control. (6) When a movable kidney gives rise to no inconvenience, an operation ought not to be thought of, and a belt need not be worn.

British Medical Journal, November 30, 1901.

A Breeding Place of Mosquitos.—A. Dunley Owen calls attention to the plantain as a place for hatching mosquitos. Each year the old leaves are cut down, leaving cup-shaped hollows which are filled with a watery fluid. Here may be found myriads of mosquitos, together with eggs and larvæ.

Case of Puerperal Fever Treated by Antistreptococcus Serum.—H. Hughes reports a case of puerperal fever in which antiseptic douches were given, but as the patient was growing worse, on the tenth day, 10 c. c. of antistreptococcus serum with digitalin 1-100 gr. and atropine 1-100 gr. were injected. Further injections of the serum were given and the patient recovered. The serum reduced the temperature, but had apparently no effect on the pulse.

A Clinical Lecture on Acute Yellow Atrophy of the Liver.—T. R. Bradshaw describes the case of a woman of twenty-four years, who up to the time of the present illness had always enjoyed excellent health. She died six days after consulting her physician for the first time. At this time she said she had caught cold, that she had nausea, and had been vomiting occasionally for two or three days. Two days later she became slightly delirious. Two days after this jaundice was distinct. Still two days later the patient became cyanosed and had stopped breathing. The heart was acting strongly, and artificial respiration was started and kept up for about four hours. On physical examination of the organs there was found to be absolutely no liver dulness in the usual position in front. There was no distention of the abdomen. The splenic dulness was unusually distinct. The tongue was coated with brown fur. The right optic disc was normal. The urine contained a moderate amount of bile. The diagnosis made was that of acute yellow atrophy of the liver. Necropsy revealed a liver weighing twenty-five and three-quarter ounces. The capsule was loose and wrinkled and numerous yellow spots showed through it. On section, the organ was mostly of a bright cherry red, with patches of yellow here and there. The writer concludes by saying that although the majority of cases of simple jaundice are among the mildest of the diseases which come under our notice, we should never look on them as trivial, as sometimes this apparently unimportant affection develops into a most formidable one.

A Case of Syphilitic Disease.—William Gowers reports the case of a woman aged twenty-five years, who was admitted to hospital having suffered from severe headache for three months. For two months she had also suffered from vomiting. She gradually became strange in manner, and later showed some loss of power in the right side, and this trouble increased. She had also had a fit of some kind. When she was examined there was considerable right hemiplegia, together with foot-clonus on the right side. Sensation was impaired in the right limb, but not abolished. The optic discs were normal. Inunctions of mercurial ointment were begun, and were followed by improvement for a few days, but this soon ceased. At the end of the week the administration of fifteen grains of potassium iodide three times a day was added to the mercury. The weakness increased, and the mercury was stopped. At the end of three weeks after admission complete paralysis of the left side came on quite suddenly. The stupor deepened to coma, and three days later the patient died. The symptoms suggested a rapid cerebral growth, but examination revealed that, although the disease was syphilitic, it was not in the nature of a growth. There was extensive disease of the arteries. The disease was most intense at the beginning of each middle cerebral artery. Another interesting point was that there was an abnormal arrangement of the cerebral vessels which had allowed a collateral circulation to prevent the symptoms which must otherwise have been present. There was also extensive change in certain parts of the cerebral substance. The severe persistent headache, afterward with vomiting, was the result of the morbid process in the vessels, extensive and unchecked. The steady progress of the symptoms was due to the slow changes in the cerebral nutrition. The collateral supply of blood saved the patient from the severity of sudden symptoms. The writer adds a warning against giving in such cases the very large doses of iodide which are sometimes employed.

Münchener medicinische Wochenschrift, November 12, 1901.

Neuritis and Polyneuritis.—R. Stintzing reviews the history of the classification and pathology of these diseases. Originally the pathological condition was considered as essentially atrophic in character. Latterly inflammatory factors have been found to exist in many cases. He gives the following nomenclature of these diseases as the most advanced in the light of our present knowledge: (1) Neuritis of inflammatory origin. Among such are the neuritides of leprosy and beriberi, and certain primary forms of unknown origin. (2) Neuritides of degenerative origin. These are divided into those of toxic origin (alcohol, arsenic, and mercury), those of infectious origin (typhoid fever, variola, puerperal fever, tuberculosis, and

syphilis), those of constitutional origin (diabetes, carcinoma, and marasmus), and those of systemic origin (following lead poisoning). (3) Neuritides of both inflammatory and degenerative origin. To these belong post-diphtheritic neuritis and some of the primary forms of unknown origin, such as Landry's paralysis.

Treatment of Seasickness.—O Rosenbach says that the method recommended by many of practising periodically deep or diaphragmatic respirations is of doubtful utility. It is very doubtful whether the employment of such respirations under the conditions in which seasickness occurs can bring about a sufficient degree of apnœa to relieve the reflex irritation present. This has been claimed as the result of animal experimentation, but the conditions under which such experiments have been conducted are not comparable to those under which seasickness occurs. The mere consciousness of constant changes of equilibrium is responsible for only a limited number of the cases of seasickness. The chief cause is the slight but constant motion of the tissue elements. The large number of measures which have been employed successfully in the treatment of this condition act not in a physical but in a psychic manner. The mere exercise of will-power is rarely able to overcome seasickness. A steady concentration of the mind upon certain objects is, however, of great benefit. Unfortunately, these means are not always successful. Recovery from seasickness, the cause still operative, takes place because the organism becomes accustomed to the abnormal movement of the tissue elements.

Osteomalacia with Tumor Formation.—Gustave Feldmann reports this case. The patient, a male seventeen years of age, gave a good individual and family history. He was a bookbinder by trade and operated a press, principally with the right foot. A deformity of the right lower limb gradually made its appearance. For this osteotomy was performed. A poor recovery was made and the affected limb was permanently weakened. General debility gradually supervened, and the patient became confined to bed. Five years after the operation, in getting out of bed, he fell and sustained a fracture of both thighs. The treatment of these was unsatisfactory, incomplete union being obtained. The year following, he passed fourteen pea-sized stones from the bladder accompanied by much "sand" and bloody urine. At about this time there occurred a fracture of the right lower limb. Subsequently a tumor appeared on the right lower jaw at the place from which a tooth had been extracted two years previously. This increased, at first slowly, then rapidly, in size. Finally the following year he complained of violent pains in the left shoulder, arm, and elbow. A tumor appeared in this location which gradually increased in size for a year and then gradually subsided. In addition to the above both knee and ankle joints have become ankylosed. The diagnosis is osteomalacia, sarcoma, and arthritis deformans.

Munchener medicinische Wochenschrift, November 19, 1901.

Pulse-Rate During the Puerperium.—Otto Aichel discusses the significance of the pulse-rate during the puerperal period. It is generally conceded that, under normal conditions, the pulse-rate during the puerperium is lower than that found during the pregnant period. Observations along this line have not, however, given uniform results, but have shown that in apparently healthy puerperal women the continuous pulse-rate may vary all the way from 40 to 100 beats per minute. In order to appreciate fully the significance of the pulse-rate during this period, three facts must be established, viz., the pulse-rate in the recumbent position (1) During pregnancy; (2) During labor; and (3) During the puerperium. The normal pulse-rate in a given case having thus been established, comparisons of great value can be made between such and similar observations during the puerperium. In many women, the normal pulse-rate during pregnancy is from 80 to 100 per minute. A continuance of this during the puerperal period is therefore of no pathological significance. The persistent increase of the puerperal over the normal pregnant pulse-rate is always an evil omen. Abnormal temperatures during the puerperium, either increased or decreased, should not cause apprehension, so long as the pulse-rate is not notably increased over that which was observed during the pregnancy. The statistics hitherto gathered with respect to the normal puerperal pulse-rate are of little value, because the principles outlined above have not been followed. Much valuable information has been lost because of the failure to make the comparisons noted. It is evident that each case is a law unto itself, and that observations to be of value from pathological, prognostic, or therapeutic standpoints must be made with this thought in view.

The Present Status of so-called Fatty Heart.—Carl Hirsch calls attention to the complex symptomatology which accompanies this condition and to the fact that the predominating symptoms vary greatly in different cases. The symptoms are, of course, dependent upon the reduced ability of the heart to perform its work, but the clinical picture in individual cases is governed by the etiological and anatomical factors present in each case. Recent researches have shown that in the production of the condition which we call fatty heart, other factors than the mere presence of fatty degeneration or infiltration of the heart muscle are at work. Such fatty changes do not stand in direct relation to the symptom-complex and form only a link in the chain of pathological lesions which are responsible for the clinical picture. The other links are arterial sclerosis, kidney lesions, etc. It is therefore erroneous to speak of fatty heart as a disease *sui generis*. If fatty non-muscular individuals present symptoms of deteriorated heart power, it is very possible that this may be due merely to an abnormal relation between the size of the body and the muscular validity of the heart. In all such cases, however, the presence or absence of arterial sclerosis and anatomical heart alterations must be carefully ascertained. In cardiac insufficiency occurring in fatty, muscular persons, arterial sclerosis, kidney lesions, and chronic myocarditis must often be considered as the chief factors in the case. The occurrence of hypertrophy in a fatty heart is not due to the mere presence of fat, but is produced by the accompanying lesions, such as arterial sclerosis. In individual cases the complete diagnosis depends upon the correct apprehension of the various pathological conditions present. Only in this manner can each case be intelligently understood. Treatment should be directed to the existing conditions, such as anæmia, nephritis, arterial sclerosis, or simple lack of cardiac muscular tone.

Uterine Lactation-Atrophy.—Under this appellation W Thorn describes the uterine atrophy which occurs in nursing women. Such atrophy may be physiological or pathological. Physiological uterine atrophy is always present during the lactation period. Its origin is due to two causes: (1) Excessive or abnormal uterine contractions, and (2) Loss of nutrition occasioned by the milk flow. The period of greatest atrophy corresponds to the period of most excessive lactation. In this physiological uterine atrophy the body of the uterus is chiefly involved. The cervix and the neighboring parts suffer only to a slight extent. The reduced liability to impregnation during lactation is not due to the cessation of ovulation, for this process continues during the entire nursing period, but is dependent upon physiological uterine atrophy and stands in direct relation to it. Under normal conditions the uterus possesses ample powers of regeneration and in due time is restored to its original nutritional condition. The return of menstruation is generally a sure sign that complete regeneration has taken place. Pathological uterine atrophy is merely an amplification of the physiological process above described. It is principally occasioned by a prolonged period of lactation in debilitated women suffering from constitutional disease or possessing a cachectic condition. Local uterine conditions of malnutrition may also play an important part in this form of atrophy. Here the atrophy may be progressive and continuous, affecting not only the body of the uterus, but the cervix, vagina, and neighboring parts. Partial regeneration may occur, but rarely does the organ return to its normal condition. The treatment of pathological uterine atrophy is chiefly prophylactic. In no case should the lactation period exceed one year in healthy women. In anæmic or debilitated women eight months should be the limit. When the atrophy persists after the cessation of lactation, constitutional measures (arsenic, iron, etc.) should be chiefly relied upon. Local treatment is rarely indicated, and, when employed, is seldom beneficial.

Berliner klinische Wochenschrift, November 18, 1901.

Early Diagnosis of Tuberculous Cystitis.—P. Asch reports two cases of tuberculous cystitis which were diagnosed in the first stage of the disease by means of cystoscopy and bacteriological examination of the urine. Both cases showed the ordinary objective symptoms of cystitis. In the first case, the urine was so clear that a diagnosis of neurasthenic cystitis had been previously made. Cystoscopic examination showed a typical tuberculous ulcer near the opening of the left ureter. The remainder of the mucous membrane of the bladder was normal. In the second case, isolated blood extravasations, surrounded by congested mucous membrane, were present. The prostate gland was enlarged. In both cases repeated microscopical examination showed the presence of tubercle bacilli in the urine. In neither case was pulmonary tuberculosis present, and the general nutrition was good. The use of the cystoscope in the initial stage of tuberculous cystitis is unattended by risk and does not unfa-

vorably influence the course of the disease. This, however, is not always the case when the disease is advanced.

Anæmia Splenica with Ascites (Banti's Disease.)—Senator says that in reality this disease is made up of a number of pathological conditions which have been understood for a long time. Banti showed the relation which the various processes bear to each other and pointed out that, when so related, they constitute the continuous steps in a single pathological process. Banti divides the disease clinically into three stages: an anæmic, a transitional, and an ascitic. The first stage has long been known as splenic tumor with anæmia. Later it has been described under the names of pseudoleukæmia and anæmia splenica. The second and third stages of the disease have been usually considered as cirrhosis of the liver with anæmia splenica or the hemorrhagic diathesis. The lesions in the spleen are of a fibro-adenoid character. Nucleated red blood cells are absent. The lymph glands are not enlarged. The disease has been usually regarded as of infectious origin, although no specific microorganism has been discovered. It has been thought by some that autointoxication from the intestinal tract is responsible for the disease. Banti thought that the ascites was invariably dependent upon cirrhosis of the liver, but Senator's researches have shown that this is not the case, for cirrhosis of the liver is not a necessary accompaniment of the disease. Ascites may arise from mechanical causes due to the presence of the enlarged spleen in the abdominal cavity. The blood changes consist essentially in a reduction of red blood cells, hæmoglobin, and leucocytes. Poikilocytosis is present and the alkalinity of the blood is increased. The tendency to spontaneous hemorrhage is very marked. This was not sufficiently emphasized by Banti, but has been noted by other observers. The diagnosis depends upon the chronic spleen enlargement and the blood condition, together with the fact that these conditions precede the liver changes. Malaria may be excluded by the blood examination, but it should be remembered that in some instances this disease has appeared as a sequel of chronic malarial poisoning. The first stage of the disease cannot be differentiated from ordinary anæmia splenica. The prognosis is uncertain. Splenectomy has been recommended as a radical method of treatment. It has been employed with success in some cases. The medicinal treatment consists in the internal or subcutaneous use of arsenic, iodine, and iron. Proper hygienic and dietetic measures should, of course, be instituted.

Deutsche medicinische Wochenschrift, November 21, 1901.

Treatment of Intubation Ulcers.—Johann Bokay reports the successful treatment of five cases after the method of O'Dwyer. This consists in the employment of tubes provided with a narrow neck and coated with a layer of gelatine and alum. In all cases in which intubation has lasted over one hundred hours, ulceration is liable to occur and the employment of these tubes is then to be recommended. The gelatinized tube is left in the larynx for five days, at the end of which time it is removed and replaced by a similar tube. This process is repeated three times, at the end of which the ulcer will usually be found to be completely healed.

The Value of Tetanus Antitoxin.—B. Mollers reports four cases of tetanus treated with antitoxin. All proceeded to a fatal termination, although one showed temporary improvement following the inoculation. In regard to the use of antitoxin in tetanus, Behring has always emphasized the fact that the initial inoculation should not occur later than thirty hours after the onset of the tetanic symptoms, and furthermore, that a sufficient amount of the serum should be used. A large part of the statistical information regarding the orrhotherapy of tetanus is of no value on account of non-compliance with these principles. In all of Moller's cases, however, large amounts of the serum were inoculated within thirty hours following the onset of symptoms, yet all terminated fatally. It is true that they were all severe cases, as evinced by the profound infection; but it is in this class of cases that orrhotherapy must show its worth if it has any. Many of the mild cases recover under former methods of treatment. Animal experimentation has shown that preventive or coincident serum inoculation is usually effectual, but in the practical treatment of the disease too much time has generally elapsed between the infection and the serum inoculation to permit the latter being of avail. In such cases the amount of toxins already produced has damaged the nervous centers beyond repair. The prophylactic use of the serum is very efficient and is to be strongly urged.

The Parasitic Nature of Carcinoma.—Hugo Ribbert considers the arguments advanced by the supporters of the parasitic theory, and shows where these are faulty and not convincing. The supposed parasites of carcinoma are believed to exist, and to be capable of multiplication only within the epithelial cell, where they produce an irritation which completely changes the biological properties of such cells. No irritation, parasitic or otherwise, is able, so far as we know, to alter the inherent biological characteristics of cells, but only to increase or decrease their normal functions. This theory also presupposes the existence of a symbiosis, so to speak, between the parasite and the epithelial cell. In other words, these organisms cannot live outside of the particular variety of epithelial cells which they attack. As in different forms of carcinoma a variety of epithelial cells is affected in order to accept the parasitic theory, it is necessary to suppose that there are a number of specific parasites. Given the existence of a parasite within a cell upon which it draws nutrition for multiplication and metabolic processes, it is certain that this condition of things must bring about a decreased vitality of the cell. In carcinoma, however, the vitality of the cell is greatly increased, and it is among the most proliferative that we know. The occurrence of metastatic tumors does not necessarily imply that they are of parasitic origin. The carcinoma cells are capable of transmission through the blood-vessels from one region of the body to another, and wherever they find lodgment they may proliferate and thus give rise to new tumors. Czerny regards the fact that carcinoma is usually a superficial growth as evidence of its parasitic origin. This does not necessary follow, as in such a location a vast number of other factors may be at work. The supporters of the parasitic theory have recently laid great stress upon the fact that animal experimentation has shown that carcinoma is a transferable disease and may be transmitted from animal to animal by inoculation. It is entirely in accord with the facts, however, to regard the tumors so produced as metastatic growths entirely similar in their origin to those which occur within the body which contains the original tumor. The fact that carcinoma is apparently on the increase is not, necessarily, proof of its infectious origin. A large part of the statistics is not based upon a pathological, but merely a clinical, diagnosis.

French Journals.

The Use of Baths of Oil of Cade in the Treatment of Psoriasis.—F. Balzer and Al. Schimptie speak of their success in treating psoriasis with the oil of cade. They advocate the following preparation: Oil of cade, 50 gm.; fluid extract of quillaja, 10 gm.; yolk of one egg; distilled water, up to 250 gm. The bath ought to last from one-half to one hour. The patient uses gentle friction on the spots affected. The writers add that they have been particularly pleased with the effects of this treatment in chronic cases.—*Bulletin Général de Thérapeutique, November 23, 1901.*

Voluminous Adenocarcinoma of the Ovaries with Ascites.—M. A. Delobel reports this case. He states that the tumor might be called a microcystic epithelioma. These cysts appear to the naked eye only as brilliant points. On section there can be seen microscopically a large number of round cavities of unequal volume and covered with cylindrical epithelium. At certain points there is the aspect of a very diffuse carcinoma. It is reasonable to surmise that this curious neoplasm has had its origin at the point of the primordial follicles, although certain authorities deny the possibility of the origin of tumors from the epithelium of the Graafian follicles. The writer notes the presence of masses of polymorphous epithelial cells in the dilated vascular cavities.—*Journal des Sciences Médicales de Lille, November 23, 1901.*

Diazo Reaction in Plague.—Parodi gives his observations in this field. He has studied ten cases of plague with respect to the diazo reaction, and eight times the result obtained has been positive. The diagnosis of all of these cases had been made microscopically. In these eight cases, the diazo reaction showed itself very early in the disease. In the two cases of plague in which it did not show, the type was so benign that the general condition of the patient seemed undisturbed and there was not the least fever. The eight cases were more or less severe with high fever and intense general symptoms. The writer adds that it is well known that plague can exist without buboes, in this form resembling typhoid fever.—*Le Bulletin Médical, November 16, 1901.*

Treatment of Facial Neuralgia by the Galvanic Currents.—Vernay concludes that the electrical treatment of trigeminal neuralgia is a curative treatment on which one may count not only in recent and slight cases, but also in serious and chronic cases, if one makes the application with an intensity and duration sufficient for the case. The current chosen should be the constant gal-

vans called the continuous current. The intensity should be at least forty milliamperes, and may be much higher, according to the case. The duration of application should vary from thirty to sixty minutes. The treatments should continue daily for from ten to thirty days, according to the case. The facial electrode should be well padded and applied to the whole region of the nerve. The treatment is absolutely harmless if the current is graduated gently and progressively at the beginning and at the end of the application. The active pole will preferably be the positive pole, although if this proves unsuccessful the other may be used, especially if trophic trouble exist.—*Lyon Medical*, November 24, 1901.

Inflammations and Tumors of the Breast.—Pinoux reports two cases. The first patient was a woman aged forty years. For some months she had been suffering with her left breast. On examination it was discovered to be bosselated and irregular, with numerous and superficial nodules. The ganglia were scarcely enlarged. Pain in the breast had been sharp in character. The diagnosis of mastitis was made and operation was not advised. Later, however, a partial operation was performed, and the microscopical examination did not disclose anything malignant. But at the end of four months the patient returned with a recurrence, and this operation showed the tumor to be carcinoma. The patient died at the end of a few months. The writer believed this to be a case of cancerous mastitis, in which the inflammatory lesions masked the epithelial. In such tumors when medical treatment does not alleviate the symptoms, operation should be performed, and this should be radical. The second patient was a woman of forty-eight years. She was affected with a tumor of the right breast. Microscopical and bacteriological examination demonstrated that the tumor was a perfectly typical encephaloid carcinoma, the center of which showed necrotic or purulent degeneration. This degeneration could be attributed only to an affection of the neoplasm by the staphylococcus albus. The infection took place by way of the milk ducts in the normal glandular acini, as well as in the carcinomatous.—*Le Bull. Méd.*, November 13, 1901.

New Apparatus and Method for Writing for the Blind.—Laborde in presenting this new method speaks of the disadvantages of the old system of Braille. There are various disadvantages connected with this method. In the first place, the blind student is obliged to learn two alphabets, two notations of figures, and two musical notations, one for writing and one for reading. This is a long, difficult, and fatiguing process for both student and master, especially for the latter. The blind student is obliged to learn to write from right to left, and to read from left to right, two cerebral processes which are antagonistic the one to the other. In order to read over anything he has written, the blind student is obliged to lift up the leaf of paper from between the plaques of zinc and copper and to turn it over, and when he begins to write again, he must exactly readjust the paper, placing it where it was in the first place. In order to make any correction, he has to go through all this process. And, finally, he cannot calculate, for in order to do that it is necessary to read and write on the same side of the paper. This new method which has been conceived by Dussaud has many advantages. By means of it the blind student writes the letters as he reads them. He has only one alphabet to learn, one notation of figures, one musical notation. There is an economy of half the time and fatigue in his education. He writes and reads from left to right. He can read over again what he has written. He can correct it, and finally he can calculate on paper. So the problem is solved which has for so long been attended with such difficulties, and characters in relief can be made by a pointer on the same side of the paper as that on which it is pressed. Cheaper paper can be employed than with the old apparatus, and the construction of this apparatus is remarkable for its simplicity and ingeniousness.—*Bulletin de l'Académie de Méd.*, November 19, 1901.

Bulletin of the Johns Hopkins Hospital, October, 1901.

Chorea with Embolism of the Central Artery of the Retina.—Henry Thomas presents the case of a young girl aged sixteen years, apparently in perfect health except for slight choreic movements, which involved the right arm and leg, and very slightly the face. The patient said that she had been unable to see with the left eye since the trouble began, but unfortunately she could give no definite account as to exactly when this blindness occurred. About a year ago, unsteadiness in the movements of the right hand attracted attention. A certain awkwardness of speech developed and the movements involved the leg on the right side. The heart was slightly dilated, with a rough blowing systolic murmur, heard at the apex. The patient said that her blindness came on suddenly, and when she discovered the defect it was as complete as at any subsequent period. Ophthalmoscopical examination confined the diagnosis of embolism of the central artery of the retina. The eye complications of chorea are not very numerous, the author says.

Carcinoma of the Male Breast.—Louis M. Warfield, in reviewing his series of cases of carcinoma of the male breast, states that the majority occurred between the ages of forty and seventy. The greatest number occurring in any one decade was thirteen in the seventh decade. As to the length of time the tumor was noticed, the longest time was thirty-five years. The shortest time was two weeks. Either breast may be affected indifferently. In a few cases, there is a history of trauma. Pain does not seem to be a prominent symptom. Ulceration is present in a certain proportion of cases. Retraction of the nipple is noted in various cases. Discharge from the nipple was noted in one case. Out of twenty-nine of the thirty-seven cases reviewed, the axillary glands were enlarged and palpable in twenty. The microscopical appearances of the tumors in both sexes are quite similar. Thus far no peculiarities of structure in the male cancers have been made out. All the varieties found in women are found in men.

A Case of Primary Adenocarcinoma of the Fallopian Tube.—Elizabeth Hurdon reports this case and gives the following reasons for the tumor being primarily tubal: (1) The uterus is normal; (2) The tube is large as compared with the ovary, ovarian carcinomata grow rapidly and attain considerable size before extension occurs; (3) There is a definite relation between the papillary masses and the tubal folds, while the ovary merely shows invasion of parts adjacent to the tube, and contains no papillary excrescences, excepting those projecting from the end of the tube; (4) The mucosa of the tube is the site of the neoplasm, the invasion of the musculature being due to extension outward from the mucosa. In carcinoma of the tube, secondary to that of the ovary, the growth usually extends from the peritoneal coat inward, and the canal may be normal or constricted, not dilated. The writer states that carcinoma of the tube has not been diagnosed previous to operation, a diagnosis of ovarian cyst or of hydro- or pyosalpinx having usually been made.

The Journal of Tropical Medicine, November 15, 1901.

Causation of Enteric Fever in India.—Andrew Duncan considers it a matter of marvel that more men are not infected with typhoid fever than is at present the case in India, considering that (1) There is a continual supply, year by year, of a large body of men most predisposed to the disease, a fresh stock of the infection agency thus being added yearly to the country. (2) This large body of men most predisposed to the disease, though living nominally in highly sanitary barracks, are yet daily exposed to the infection of typhoid fever contained in the liquids they imbibe in the bazaars and in the dust of the station, and spread broadcast through the agency of flies. (3) The country soil is, moreover, becoming yearly more and more impregnated with the typhoid bacillus. The remedies suggested by the author are burning the stools of the sick, disinfecting the urine, and, most important of all, compulsory inoculation. He gives the statistics in cases of inoculation, which, he thinks, prove it to be of value as a preventive measure.

Tropical Food Adjuncts; Prevention of Disease; Spices.—J. M. MacKnight finds that in tropical countries between latitude twenty-three degrees south and twenty-three degrees north of the Equator, the inhabitants use spices daily with their food as we use pepper. A certain beneficial effect is caused to the digestion, viz., stimulant and carminative. But there is a secondary effect, which is perhaps even more beneficial, seen in the fact that the volatile oil passes out from the body, mostly unchanged, through various channels, but chiefly through the lungs and skin. So that in the tropics Nature has provided antiseptics which, in passing out by the lungs and skin, kill the hurtful microbes which might be breathed in, and also prevent, to a great extent, the attacks of mosquitos. It is a well-known fact that insects, including mosquitos, dislike volatile oils, and will probably not attack an individual using spices as a food adjunct. It is interesting to note that spices grow when there is a high rain fall combined with much heat—conditions under which malarial influences prevail. The author quotes various authorities in regard to the antiseptic, antipyretic, and other actions of aromatics.

Society Reports.

THE PRACTITIONER'S SOCIETY

166th Regular Meeting, Held on Friday, November 1, 1901.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR

A Further Report on "Beatson's Operation," with Presentation of Cases.—Dr. ROBERT ABBE showed three cases of recurrent carcinoma of the breast treated by oöphorectomy. Two of these he had already shown at the May meeting of the society. He also reported four additional cases of the same kind. The detailed history of each is as follows:

CASE I.—A single woman, forty-two years old; menstruating. She was operated on eighteen months ago by Dr. Henry C. Coe for a malignant mammary carcinoma. Ten months later she presented herself with a recurrence and another malignant growth in the opposite breast about the size of a hen's egg. The recurrence around the scar consisted of about a hundred small nodules, covering an area 4 x 7 inches. The central part formed a mass in a solid cake, which was attached to the ribs and invaded the pleura, with evident recurrence within the pleura. There was a pleural effusion rising to the level of the fourth rib. The infraclavicular glands on the operated side were involved, and on the opposite side a large chain of glands extended from the breast to the axilla. No operation was done upon the recurrent disease, but on March 4 of the present year both ovaries were removed. There was a quick convalescence, and in one week slight changes were noticed in the nodules, near the old mammary scar. In two weeks most of the nodules were becoming pale and flattened, the flattening resembling umbilication; in some a ring of hard tissue remained. In four weeks almost all the nodules had disappeared, and the tumor in the opposite breast was becoming smaller. At eight weeks, when the patient was shown at the Practitioners' Society, every vestige of cancer that could be felt had gone, and the invaded tissue showed atrophy. The fluid and dulness, however, remained. The disappearance of the cancer-recurrence was in every instance in the order in which the nodules had consecutively appeared. The last to disappear were the axillary glands on the side not operated upon. The patient was next seen in midsummer, four and one-half months after oöphorectomy. She seemed in perfect health, and no trace of recurrence could be felt. The fluid level in the chest seemed an inch lower, but an examination was not convincing. The patient was not seen again until three months later, October, 1901, when it was found that she had aphonia and a little hacking cough from pleural extension; she did not look as well and had lost weight. Palpation of the atrophied spots, representing the original nodules of recurrence, showed a little thickening of some, but at least two-thirds of the recurrent nodules had permanently gone. The opposite breast, from which the tumor entirely disappeared, showed enlargement and a diffused fibroid thickening, without pain or nodules. The patient had taken thyroid after operation, but had taken none during the two preceding months. She was advised to renew this. Since then there has been no material change in her condition. The dulness in the chest at present has not changed in six months.

CASE II.—Woman, nearly seventy years old, with a typical mammary cancer which was removed two years ago. There was a recurrence of six nodules in the skin, about the size of the end of one's finger, with a round, malignant ulcer involving the lower part of the scar. It was about an inch and one-half in diameter and bedded upon the pleura. Oöphorectomy was done on April 15, 1901. Retrograde changes were noticed in the ulcer, which rapidly healed in eight weeks. The recurrence nodules diminished and came to a standstill. At the present time, six months after operation, a renewal growth of the nodules is apparent, and the ulcer, which has remained healed, is now showing a slight tendency to thicken. The general condition of the patient is excellent, and on the whole retarded growth and excellent general health may be credited to the oöphorectomy.

CASE III.—Woman, aged seventy years, very spare, with hopeless, inoperable disease of the left mamma. There was a tumor, two and one-half inches in diameter, which was heaped up about the nipple in hard purplish nodules, almost ready to ulcerate. From the edges of the mass to the highest point in the axilla was a compact chain of large and small glands, which terminated above and beneath the pectoral muscles. In a large group below the clavicle a series of small lymphatics could be discovered. Surgical interference had been refused her, and Dr. Abbe offered oöphorectomy as an experiment. Two atrophied ovaries were removed on May 16, 1901, and at present, six months later, the tumor is positively smaller and flatter, and some of the purple masses above the nipple have wasted. The axillary and other gland masses are estimated half the bulk that they were before the operation. The general appearance of the patient is excellent; she eats and sleeps well.

CASE IV.—The patient was a woman whose breast had been removed by Dr. Abbe for carcinoma in September, 1899. Eighteen months later, she presented herself with four nodules of recurrence about the scar, and a small infraclavicular group of lymphatics. Last May (1901), her ovaries, which were normal, were removed. Two months later, the patient reported that she was in better health than in the previous two years. The nodules appeared to be a trifle smaller. The patient has gained ten pounds in weight during the summer. Two nodules have since disappeared, the others remain seemingly unchanged.

CASE V.—The patient was a woman of fifty, who was operated on in December, 1900, for a most malignant type of mammary cancer. In March of the following year she had an extensive recurrence at the root of the neck; this involved the lymphatics and extended down to the pleura. In May, there was a recurrence in the costosternal end of the scar, three inches by four in length, and others extending to the posterior triangle of the neck, and along the border of the shoulder blade. This case seemed to be in every way most unpromising, both on account of the rapid recurrences, the dusky appearance of the tumor, and its infiltrating attachments. The patient was offered oöphorectomy experimentally. It was done, and for a month there seemed to be a slight shrinkage in the size of the tumor; but its activity was then renewed, and she left the hospital no better. Five months after the oöphorectomy, she died from the natural progress of the disease. No harm or gain can be attributed to the oöphorectomy in this case, which, from its profoundly malignant aspect, would have been fairly excluded from even experimentation, except that in a new field of work one may legitimately offer the choice to the patient.

CASE VI.—The patient was a woman of forty, who was operated on fifteen months ago for mammary cancer. There was a recurrence, one year later, above the collar-bone; for six months the patient had been losing flesh rapidly, and for two months she had hectic fever, her daily afternoon temperature being 101° F. This prolonged hectic was not accounted for by anything observed in her physical condition, unless possibly a general carcinosis. Dr. LeFevre had long watched the patient and excluded pulmonary tuberculosis by many examinations. There was no sputum. Pelvic examination showed ovarian enlargement. The presence of the recurrent cancer mass at the root of the neck, with ovarian enlargement, warranted experimental oöphorectomy, which was done on May 22, 1901. The right ovary was found to be four times its normal size, and three-fourths of its bulk was in a cancerous condition. The left ovary, which was normal, presented a cancerous nodule the size of a bean.

One month later, the mass at the root of the neck was diminished in size, but subsequently it increased, and several other nodules appeared. Her hectic condition continued without any pulmonary evidences. She died without showing any gain from the oophorectomy. The disease had evidently been widely disseminated before operation.

CASE VII.—This patient presented herself the latter part of June of the present year with a tumor of the left breast. It was a hard, carcinomatous mass, more than three and one-half inches in diameter, and associated with marked axillary glandular enlargement. This, with a complex pelvic tumor, was giving her much distress. The pelvic tumor was first removed in order to watch the effect upon the breast. The uterus presented a large, fibroid tumor. The left ovary was enlarged to the size of a small cocoanut and solid to the touch. The right ovary was also large and hard. A pathological examination revealed carcinoma of both ovaries. The patient presented extreme pallor before the operation. She left the hospital improved in general health, and spent the summer in the country, where she gained in every way. Four months later she returned, and asked to have the mammary tumor removed. A marked reduction in the size of the tumor and the glandular masses was apparent to all who examined her. Careful measurements of the tumor, made four months after the oophorectomy, showed a reduction of at least one-third in all diameters, as well as in thickness. The axillary masses were correspondingly reduced. In view of the marked wasting of the morbid tissues and the good health of the patient, she was advised to wait and remain under observation.

Dr. Abbe said that the seven cases reported above were presented for criticism. From a close observation of them, he felt justified in saying that there are some surprising results shown in five of the seven cases, proving that a marked ovarian influence extends to the mammary tumors and the adjacent lymphatic deposits of morbid cells. In these five cases there was unquestioned arrest and retrograde change in the morbid growth. In the first case, a startling disappearance of all the morbid tumors took place within eight weeks after the ovaries were removed. This same result has been obtained by other operators (Beatson, Boyd, and Herman), in occasional cases, in some of which the disappearance has continued for many months, and in one case three and one-half years.

Dr. Abbe said that in two cases where he removed the ovaries and not the breast tumors, because of the extensive involvement of the latter, there has been a slow but progressive retrograde change in both the cancer tumors and the glands. In all five cases the observation that the general health is brought to a higher standard is borne out. The cases so far operated upon have been of a particularly bad type, and if selection were to be made, there is evidence that, when the recurrent invasion has extended beyond the lymphatics adjacent to the breast, there is little hope of reaching the disease by ovarian influence. If, in the future, one were to select cases which would present more hope, one would choose those having no internal metastatic pleural involvement.

The interest in the recent observations of the effect of the removal of the ovaries for mammary tumors has been so fairly and candidly studied by the few operators who have followed Dr. Beatson's lead, that rarely has a new idea in surgery been placed before our notice with less flare of trumpets. In recent correspondence with Dr. Beatson, he wrote Dr. Abbe as follows: "I am satisfied of its usefulness, and sometimes almost marvelous effects looking to the disease dealt with, and its usual course. The cases are of value in my eyes, as to the cause of the disease, and hence their importance apart from any therapeutic effects." One sees in this the fascination the idea has for him in proving the striking control of mammary morbid growths by ovarian influence.

That this control exists in fact is attested by every operator who has experimented in this field. Candid criticism of the cases reported shows that many are favorably affected in slight degree, and some wonderfully so. In most this gain is transient, varying from a few months to many months, as far as the evidence of disease goes; but in all there is a uniform gain in general health. To witness the startling phenomenon of cancerous tumors and recurrent nodules slowly or rapidly melting away, like syphilitic lesions under the administration of iodide of potash, is so contrary to the accustomed observation of surgeons that men of ripe experience have already spoken of it as "like romance." Yet, over the whole hangs a veil of some disappointment that the gain is so little in some and so transient in others.

Dr. Beatson advises the use of thyroid extract in conjunction with the surgical procedure, and believes he has seen additional benefit from the use of it in affecting the metabolism of tissues and giving tone to the body cells. The most speedy and notable changes in mammary cancer are seen when ovaries are removed from patients still menstruating. One such case lately reported by Dr. Beatson will bear quoting, inasmuch as few have been operated on where the whole tumor was left for observation. The case referred to is the following:

The patient was a woman forty-four years old. The right breast stood out from the chest with a fixed, immobile look. It had a tense and glazed appearance, while the skin all over it was of a dusky red-bluish color, and seemed as if it was on the point of ulcerating. Enlarged glands could be felt in the right axilla above the clavicle and up the mastoid muscle. In the left breast there was also a suspicious mass, and an enlarged gland in the axilla. Changes in vascularity and size soon followed removal of the ovaries. Six months after, a very interesting and remarkable state of matters existed (to quote Dr. Beatson). The large and tense mamma that was previously covered with dusky skin and seemed on the verge of ulceration had practically disappeared, and its place was taken by a small, dense, flattened cicatricial mass. Close around it were still a few pea-like, hard nodules, but the skin generally on the adjoining thoracic wall was free from disease, and what seemed most remarkable was the entire disappearance of the glandular enlargement previously noted.

Dr. Abbe said it was his belief that such results may reasonably be expected in similar cases, but as yet few have been tried. At the present writing, one may affirm that ovarian influence over mammary tumors has been proven, but adequate explanation has not yet been given, unless Beatson's tentative theories are accepted.

Extensive Cancer of the Lip.—In connection with the general subject of operative relief for malignant disease, he further remarked that he had been fortunate in following three cases of most malignant cancer of the lower lip, which he operated on in 1884 and 1885, and which remained well after fifteen years.

In one case, two-thirds of the lip had been destroyed to the line of the gum by caustics applied both for the original epithelioma and for two subsequent recurrences.

A recurrence again took place and he sought surgical aid. A marked epitheliomatous mass was spread along a part of the scar, and the constant drooling from absence of lip was a distressing sight. I excised the growth, did three plastic operations, and restored the mouth. After fifteen years, he remains well and free from recurrence. The second and third cases involved the entire breadth of the lower lip in solid cancer mass. I removed more than the entire breadth of the lip, and the mucous membrane to the line of the gum—doing plastic operations to build up new ones which were entirely successful. After fifteen years, these men have had no recurrence of the disease.

In a large number of cases, where I have removed less

extensive disease of the lip. I have been able to see the patients from time to time in years after, and can say truly that, while some have recurred, the great majority have secured immunity from disease by operation.

I have a growing conviction, therefore, that in this form of epithelial cancer more than in almost any other situation, we can attain radical cure.

He then exhibited a female, ten years old, who had been operated upon by him nine years ago for sarcoma of the kidney. The case in certain respects is unique, and he had shown her at various times since the operation. When she was first brought to him her weight was fifteen pounds, and the tumor, upon its removal, was found to weigh seven and one-half pounds. The growth was attached to the upper part of the kidney, and when it was dragged out of the abdomen there was found hanging from it a pendulous mass which proved to be the flattened, pale kidney. The kidney was divided between its middle and upper thirds, and as the lower portion of the organ appeared to be absolutely healthy, it was put back into the abdominal cavity, after suturing, together with the renal vessels. No line of demarkation could be found between the kidney tissue and the tumor. Since the operation the child had never had a sick day, and she was apparently enjoying excellent health at present.

Dr. WILLIAM M. POLK asked Dr. Abbe what was the best result thus far obtained by the Beatson operation?

Dr. ABBE replied that one case had gone three and one-half years without any signs of a recurrence. Most of the cases, however, were recent.

Dr. POLK said this subject was still in an experimental stage. The fact has long been known that removal of the ovaries will produce an atrophy of the mammary glands. This atrophy is more marked in some cases than in others, and it is proportionate to the age at which the ovaries are removed. Oöphorectomy in a woman of thirty will cause a more marked atrophy of the mammary glands than in one of forty. The influence of the ovaries upon the nervous system and the system as a whole is also well known.

Dr. Polk said that soon after he heard of Beatson's operation he looked over his records, and found one case, a woman of forty-four, in whom carcinoma of the breast developed subsequent to the removal of her ovaries. We also frequently see carcinoma of the breast develop in women of sixty and over, long after the activity of the ovaries has ceased. While we have every reason to believe that any growth connected with the breast, or with the genital system, will atrophy after removal of the ovaries, we have, so far, no grounds for the belief that the atrophy will be permanent. A case has been reported in which thyroid extract seemingly produced a very markedly beneficial effect upon a carcinomatous uterus, but in all these cases the permanent result is still a matter of speculation. At the same time, anything that offers any measure of relief to these patients should be availed of, and the subject is certainly worthy of further experimentation.

A Case of Osteomyelitis of the Femur and Tibia.—Dr. V. P. GIBNEY showed a boy, seven years of age, upon whom he had done a number of operations for an extensive osteomyelitis involving the right femur and the tibia on the opposite side. When the patient first came under the speaker's observation, about four years ago, the disease was found to involve the entire shaft of the femur, from the condyles to the trochanter, and about two-thirds of the shaft of the tibia. The ends of the bones were not affected. The destruction of bone was very extensive, and on account of the desperate condition of the patient, the two limbs were operated on simultaneously, Dr. W. R. Townsend taking one side, and Dr. Gibney the other. A free incision was made over each bone, and the diseased tissue removed as thoroughly as possible. The limbs were then put up in plaster-of-Paris, drainage being secured through a fenestrum cut in the dressing. Following the operation, the boy made an uninterrupted convalescence, and there was a rapid reproduction of bone in the portions of the shafts that had been removed. At the present time, the bones are quite firm. There is practically a difference of about half an inch in the length of the two limbs, while relatively there is none. Last spring, a slight necrosis recurred in the affected femur; this was curetted and drained.

Dr. Gibney said this boy now has two good limbs, in spite of the extensive destruction of bone tissue. The case illustrates to what extent we may hope for the reproduction of bone from the periosteum.

Dr. GEORGE F. SHRADY said the case shown by Dr. Gibney called to mind one of his own. It was one of acute necrosis of the humerus, necessitating a resection of the entire shaft of the bone; the periosteum was saved and drainage secured by forced extension of the limb. Complete reproduction of bone followed the operation, and there was only one-eighth of an inch of difference in the length of the two arms. In the course of the operation, the musculo-spiral nerve was accidentally severed and had to be sutured. The patient subsequently recovered good use of the arm and was able to follow the occupation of a shoemaker. The case was another illustration of the remarkable power the periosteum has for the reproduction of bone.

Optimism vs. Pessimism in the Surgery of Malignant Disease.—Dr. ROBERT ABBE presented, in connection with his paper, a girl ten years old, upon whom he had operated for sarcoma of the kidney nine years before.

Dr. CHARLES STEDMAN BULL said that, in his opinion, the favorable view expressed by Dr. Abbe regarding malignant disease of the upper jaw could not be extended to those cases in which the orbit is involved. The speaker said he had never been able to give a favorable prognosis in a case of malignant disease of the orbit, on account of the various deep cavities connecting with it, and the amount of bony tissue involved. About three years ago he tabulated 120 of these cases, seventy of which he was able to trace, and in that number there were only three in which the disease did not recur. The subject came up for discussion at a recent meeting of the American Ophthalmological Association, and Dr. Bull said he was surprised to learn how many of the men who took part in it held very pessimistic views in regard to malignant disease in that region of the face. Whether the disease begins in the orbit, or in one of the sinuses communicating with the orbit, it is almost impossible to eradicate it entirely, and an operation is usually not only followed by recurrence, but it shortens the period of quiescence, hastens the subsequent development of the growth, and by just so much shortens the life of the patient.

Dr. GIBNEY said he had recently had the misfortune to see quite a large number of cases of malignant disease involving the bones, particularly the femur and humerus. These are often mistaken for cases of joint disease. In spite of very radical treatment in these cases, amputation at the hip or shoulder followed by the use of toxins; there is, in so large a majority of these patients, such a prompt recurrence that one's pessimism is apt to get the better of one's optimism.

Dr. SHRADY said the point raised by Dr. Abbe that in the removal of a cancerous breast a wide margin of skin should be excised, could not be too strongly emphasized. Lately, the speaker said, he has been in the habit of doing a double flap operation, in order to cover the large exposed areas that are necessarily left after thorough extirpation of the breast. By this method, he had found that he could delay a recurrence for a much longer period than by any other method. He was induced to resort to this plan on account of the fact that almost all recurrences were in the skin in the neighborhood of the scar. In his

ex[illegible] they occurred there at least three times as frequently as the axilla.

Dr. Shrady said that the extreme malignancy of sarcoma of the jaw is well recognized by all surgeons, and he could recall only one case of recovery after extirpation. The patient was a woman, forty-five years old, upon whom he operated nine years ago, and up to the present time there had been no signs of a recurrence. The entire left side of the jaw was removed.

Dr. Shrady said that Dr. Gibney's reference to sarcoma of the thigh called to mind a case of spindle-celled periosteal sarcoma of the inner condyle of the femur which came under his care nineteen years ago. He did a high amputation, and the man has remained free from recurrence to the present time.

Dr. Beverley Robinson said he could recall a few cases of carcinoma of the breast seen in private practice, where the patient's condition was not especially benefited by operation. It is possible that operative interference in these cases was postponed too long, and the question arises whether it is desirable to operate as a last resort in these extreme cases. This same question applies to malignant disease of various internal organs, such as the stomach and intestines—whether an operation adds materially to either the life or happiness of these patients.

Dr. Joseph D. Bryant said he belonged to that class of surgeons who regard malignant disease with a great deal of optimism. In order to diminish the mortality of this disease below the present rate, we must inculcate into the minds of all persons the importance of early operative interference. Any lesion characteristic of a tumor, or any otherwise unusual manifestation, should at once be brought to the attention of the physician or surgeon with the view of an early diagnosis. The important point is that prompt relief should be sought following early diagnosis.

The fact that in one person a malignant tumor may be permanently eradicated, while in another a similar growth removed with just as much thoroughness will promptly recur, probably depends largely on the human soil in which the disease is planted. We can all recall cases of extended malignant disease which was permanently eradicated by simple operative measures, and, no doubt, in such cases the patient himself contributed quite as much to the result as did the surgeon. The condition of the patient by reason of age or tissue in vulnerability was such that recurrence was not favored. This fact should encourage us to attack many of these tumors, even when the outlook is discouraging. While the life of the patient may not be prolonged by the operation, his sufferings will be alleviated.

Dr. Clement Cleveland said that in his branch of surgery, which was wholly confined to gynecological work, his experience with malignant disease had led him to be very hopeful. If a case of carcinoma of the uterus is dealt with early in the course of the disease, the hope of long freedom from recurrence is almost assured. The reason why so many cases of cancer in the pelvis recur is that they are not seen early enough. Either the general practitioner does not report the case soon enough, or else the woman, because of her natural modesty or fear, fails to reveal her symptoms. Dr. Cleveland said he had seen many cases of cancer of the uterus which were operated on, and were followed by a prompt recurrence. On the other hand, he could recall cases where the patients remained free from recurrence for many years. He spoke of one case, a woman who was operated on for carcinoma of the cervix ten years ago; she is now seventy-two years old, and is apparently perfectly well. Even if we are not able to effect a permanent cure in these cases, the amelioration of symptoms is often very striking. It not only relieves the pain and other symptoms, but also distress of mind.

Dr. William M. Polk said his experience in connection with this subject was largely confined to malignant disease of the uterus and its appendages, and to a few cases of breast cancer. In the main, the speaker said, he agreed with Dr. Abbe. The question of soil, as suggested by Dr. Bryant, is also very important. We all know that a woman of sixty who has beginning cancer is much less likely to have a recurrence after a primary operation than a woman of forty. The functional condition of the affected organ adds enormously to the danger of recurrence. The point that appeals to every surgeon is the kind of life these poor sufferers have to lead with a cancer of the breast or uterus. To many of them it is a living death to go around with a sloughing mass, or a vaginal discharge, which makes her objectionable to herself and to other people. Thus, keen mental agony is added to her actual physical suffering. Whether we are able to promise these patients a cure or not, we are certainly justified in advising them to undergo the risks of an operation which will at least make them more comfortable. As an illustration, Dr. Polk mentioned the case of a woman who suffered from carcinoma of both breasts. After the operation she was free from pain, and when the disease finally recurred in the mediastinum, death resulted from complicating cardiac and pulmonary symptoms, without the slightest evidence of the disease which was so offensive to herself and her friends. Merely on palliative grounds, therefore, an operation for malignant disease in certain regions of the body is entirely justifiable.

As regards cancer of the body of the uterus, Dr. Polk said, if such a case can be gotten hold of within two or three months after its onset, the chances of permanent relief are just as good as in epithelioma of the lip. In cancer of the cervix, however, the case is different. In that region the lymph vessels are so much more abundant that a rapid transmission of the disease takes place. The only hope for a cure in such cases lies in a very radical operation, opening the abdomen, ligating the internal iliac on both sides to prevent hemorrhage, and then clearing out the floor of the pelvis, taking out the uterus together with the diseased cervix, and, if need be, the upper third of the vagina. If we wish to cure a case of cancer about the cervix in a woman who is still menstruating, that is the only procedure which affords the least hope of permanent relief. Of course, such a radical operation means fatal termination in some cases—perhaps 1 or 2 per cent. die as the result of shock.

Dr. Abbe, in closing the discussion, said that in the treatment of cancer the surgeon must appreciate the fact that he is dealing with a terrible disease, which is bound extensively to ravage the parts unless it is thoroughly removed; and to do this requires the utmost coolness, judgment, and skill. Of late years, the theory has gained ground that cancer, at the outset, is essentially a local disease, and that thorough removal is possible.

Obesity.—For the relief of this condition, C. M. McLean advises salines to keep the bowels relaxed and strychnine for toning up the heart and nervous system. The heart may perhaps require digitalis. Except to meet special symptoms, it is probably unwise to give drugs in obesity, though potassium iodide will, undoubtedly, reduce the flesh in many cases. The treatment by Vichy and Kissingen salts may succeed in some cases. This treatment in a number of cases has produced greatly increased arterial tension and marked irritability of the nervous system. Personally, the author has little faith in the Kissingen-Vichy treatment. Oertel's treatment, though good in some cases, will not do in others. The carbohydrates must be greatly reduced in all cases. Sweets should be absolutely forbidden. Not more than thirty ounces of fluid should be taken in a day. In plethoric cases, the amount of food should be greatly reduced. It is easier to keep away from the table than sit down with others and only eat a few things.—*Maritime Medical News.*

NEW YORK ACADEMY OF MEDICINE

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, November 29, 1901.

A. BROTHERS, M.D., CHAIRMAN.

Etiology of Puerperal Fever.—Dr. A. ERNEST GALLANT discussed this topic. He said that bacteria occurring in the vagina are ordinarily saprophytic. The most common means of implanting bacteria in the vagina at confinement was the frequent examination of the patient per vaginam, though lack of cleanliness about the patient and bedclothes, and failure to remove the hair from about the external genitals before performing obstetric operations, were also common causes. According to some authorities, the antepartum bath distinctly favors the introduction of bacteria because the latter are washed off the surface of the body into the water, and the water is carried into the vagina. The bacteria, on gaining entrance to the system, produce toxins, and it is probable that the toxæmia arising in this way is accountable for the phenomena of puerperal fever. The streptococcus pyogenes was nearly always the active agent in producing puerperal endometritis. With the exception of the gonococcus, bacteria cannot vegetate for any length of time in the secretions of the genital tract. The opinion was gaining ground that fever and leucocytosis are salutary processes, and if this is so, the fallacy of attempting to reduce the fever is evident.

Treatment of Puerperal Fever.—DR ROBERT A MURRAY took up this part of the subject. He said that there are distinguished clinically two forms of puerperal fever, viz., (1) The saprophytic form with necrotic changes in the uterus and vagina and with vulvar lesions, and (2) The lymphatic form, affecting the system early, and associated with comparatively small local lesions. With the first symptoms of puerperal fever, the physician should inspect the parturient canal by the aid of a speculum, and should apply to necrotic patches strong solutions of nitrate of silver or of carbolic acid. Of course, any retained secundines should be removed. Where the lochia are at first foul-smelling and the placental site is rough, there is a mixed infection, and the first step should be to empty the uterus, employing the sharp curette for this purpose, and then the parts should be cleansed by irritation with a solution of 1 to 5,000 bichloride of mercury. Ergot should be given internally to keep the uterus well contracted, and strychnine and alcohol should be given to combat the toxæmia. In some of the more profound toxæmic conditions the lochia might not be foul, but merely scanty, and associated with indurations in the broad ligament. If peritonitis were present, there would soon be vomiting of dark, ill-smelling matter. Where the infection had already extended beyond the uterus, curettage would usually give rise to a chill and would increase the fever. The indications here were to support the strength and increase the activity of the emunctories, in order to favor elimination of the toxins. Liquid food should be given in small quantities at short intervals, along with alcohol to the point of producing its physiological effect. If the alcohol were not given in this way, it was useless. The tincture of veratrum viride and the tincture of digitalis might be given to strengthen the heart; the bowels should be kept open by means of salines, given by the mouth or by hypodermoclysis, and rectal irrigation should be resorted to. Abscesses should be opened, and phlebitis should be treated by the local application of belladonna ointment and ichthyol, and absolute rest enjoined. He believed that many cases would be saved if hysterectomy were done, and hence in bad cases of puerperal fever he advised consultation with an operating gynecologist. Antistreptococcus serum had not yielded favorable results, and the most disappointing fact in connection with that treatment was that one form of antistreptococcus serum would prove useful in certain varieties only of septicæmia, while it might be distinctly harmful in other varieties.

Surgical Treatment of Acute Puerperal Sepsis.—Dr. HIRAM N. VINEBERG was the author of this paper. He said that he had long been of the opinion that acute puerperal sepsis should be treated on the same surgical principles which govern the treatment of sepsis in other portions of the body. It was an antiquated notion that general puerperal sepsis is necessarily fatal, and that operation should not be undertaken. One frequently met with cases of puerperal sepsis which do not progress favorably under curettage and irrigation, and where it seemed proper to do an exploratory laparotomy. By such a procedure one could often detect the source of infection and remove it. If the exact source of the infection could not be discovered on careful inspection, and yet the uterus was enlarged to about twice its normal size, the surgeon would be justified in removing the uterus. The presence of placental remains in the uterus was not always indicated by a patulous os and fetid lochia. He was disposed to think that at the present time too much attention was given to the bacteria, and too little to the lesions present in puerperal sepsis. A case of puerperal septic peritonitis should be treated surgically just as one would treat a case of septic peritonitis from other causes, but irrigation and drainage did not seem to him sufficient; the uterus, the fountain-head of the sepsis, should be extirpated. All were agreed that when pus is present it should be evacuated.

Non-Septic Puerperal Fever.—Dr. J. CLIFTON EDGAR opened the general discussion. He called attention to the fact that all fever occurring in the puerperium does not mean sepsis, and does not mean that curettage must be done. He was not accustomed to consider that a puerperal woman has fever unless the temperature rises above 100.5° F. He divided puerperal fever into septic and non-septic fever. The former cases often arise from constipation, reflex irritation, intercurrent disease, and neurotic conditions. He had completed a study of fever in the puerperium in 2,200 cases. A rise of temperature to 100.5° F., or over, occurred in 405 cases, or 18.4 per cent. In 204 of these cases the fever had lasted only a few hours, and in only seventy-two had it continued for more than three days. Of the non-septic cases of fever, the elevation of temperature had apparently been due to constipation in 259 cases, or 63.95 per cent.; to reflex irritation in 142 cases, or 10 per cent.; to complicating disease in twenty cases, or 4 per cent.; to neurotic conditions in one case, or .24 per cent. He looked upon fifty-five cases of fever, or 12.58 per cent., as of septic origin, while in twenty-five, or 6.91 per cent., no cause could be assigned. A common source of reflex irritation was the pain resulting from the distention of the breasts with milk in primiparæ.

Treatment.—The most important preventive measure was the avoidance of frequent examinations and the exercise of great care in sterilizing the hands. He took the position that there is no special or curative treatment for all varieties of puerperal infection, and that it must vary with each variety and be carefully adapted to the individual case, often after bacteriological investigation. The curette had played an important part in the treatment of puerperal endometritis, but the opinion was gaining ground that the curette, while very useful in abortions, was apt to do more harm than good after full-term deliveries. Good results might be obtained without curettage, even in cases in which the sepsis was demonstrated to be due to streptococci. In cases of puerperal septic endometritis, the remains of the placenta should be removed and intrauterine irrigations given in the more severe cases. If intrauterine treatment were not beneficial in a short time, it should be discontinued. Great care should be taken not to injure the maternal soft parts by the manipulations. In the acute lymphatic form of

sepsis the progress of the disease was so rapid that little could be done in the way of treatment. He had tried the Credé ointment in a number of cases, but had been unable to satisfy himself that it had influenced the disease at all.

Dr. H. J. Boldt said that he had been disappointed that Dr. Vineberg was yet unable to lay down any more definite indications for operation in cases of puerperal sepsis. Recently, Dr. Boldt said, he had been having all of his cases examined bacteriologically, but without having any new light thrown upon this subject. He had operated many times in puerperal sepsis, yet he had always had a lurking suspicion that those who had recovered might have done so without having been subjected to the operation. In a case in which there had been chills and bacteria in the blood, if the evidence of sepsis were confined to the uterus, he certainly would not hesitate to do hysterectomy.

Conservative Treatment Advocated.—Dr. H. J. Garrigues advocated the discarding of the term puerperal fever. It was well enough, he said, to use this term at the time when it was considered that puerperal fever was a specific disease, but now the term was applied to any fever occurring in the puerperium. In his opinion, it was not possible to base treatment of puerperal infection on the findings of the bacteriologist, and he believed that this infection is essentially a medical, and not a surgical, disease. He laid great stress upon cauterization with zinc chloride as soon as ulcers are present in the birth canal, and presented an appearance even resembling diphtheria. He still thought the best treatment for peritonitis is the opium plan, though admitting that in beginning peritonitis it might occasionally be an advantage to make an incision into the posterior cul-de-sac of the vagina and establish drainage in that way. Occasionally, also, in cases of general peritonitis, it might be justifiable to evacuate the serum and pus. So far he had not seen a single case recover which he had treated with the Credé ointment. Of late, a solution had been recommended instead of the ointment. It was to be injected into a vein. He had used the solution in this way on a case only yesterday, and while it had had an excellent effect on the temperature, the patient had died to-day. He was disposed to think that some good might result from the use of nuclein, for it does not do the patient harm, and there was some reason to believe it might do some good. Hypodermoclysis with normal salt solution was useful in these cases. Alcohol was exceedingly useful, but it must be given in large quantities—from twelve to twenty-four ounces in the twenty-four hours. The patient must be made to take plenty of food, both liquid and solid. He was absolutely opposed to the use of the curette, although he had used it many times in the past. If there was reason to believe that something had been left in the uterus, this organ should be dilated so as to admit two fingers, and by counter-pressure with the other hand the cavity might be explored and retained portions removed. If pus were present in the pelvis, drainage should be established through the vagina. He did not think hysterectomy indicated in cases of puerperal sepsis. In his opinion, bichloride of mercury was very dangerous when used as an injection into the vagina or uterus.

Vaginal Examinations Not to Be Feared. Dr. S. Marx thought it would be safer to assume that all fever complicating the puerperal state is due to puerperal sepsis until proved to be otherwise. It should not be forgotten that some very severe forms of puerperal sepsis are associated with little or no rise of temperature; the pulse is a better indication of the puerperal patient's condition than the body temperature. He was more inclined to make vaginal examinations during labor than were other practitioners, because while abdominal palpation seems very clear to some minds, it is far from being so to others. He would not advocate unnecessarily frequent examinations, but he was opposed to the management of labor according to the up-to-date view of the mere laying on of hands. Where there was a distinctly acid vaginal discharge, he felt that the parts were well protected against bacterial invasion, and hence he carefully avoided the use of douches or other interference; but when there was a free yellowish alkaline discharge, he prepared the vagina for labor with as much care as for a major operation. He agreed with Dr. Garrigues as to the usefulness of applications of chloride of zinc to local lesions in the early stage of puerperal sepsis.

Success with Antistreptococcus Serum.—The first twenty-five cases in which he had used Marmorek's antistreptococcus serum had all terminated fatally, and he had been informed that this serum deteriorates rapidly, and that then it is probable that it actually aggravates the patient's condition. More recently he had been using serum supplied by various American manufacturers, and had secured several apparently brilliant results. He now believed there was a distinct field for the administration of the antistreptococcus serum. He had made use of 10 c.c. of the serum every three hours. He had had one undoubtedly successful case with the Credé ointment, but since then he had used it several times with no result.

Serum and Ointment Treatment.—Dr. S. S. Jones said that in very many cases there would be no fetid lochia, and no very marked patulousness of the os in the first few days of puerperal sepsis. A slight rise of temperature twelve hours after labor might almost be considered normal, but such a temperature after the first twenty-four hours should be carefully investigated. The vagina should be carefully inspected, and if nothing were found, digital exploration of the uterus would often enable one to detect and promptly treat the source of the sepsis. He did not think one was justified under any circumstances in introducing the hand into the vagina and the fingers into the uterus without having first carefully determined by inspection the condition of the vagina. It was probable that some of the early antistreptococcus serum and the early Credé ointment was inert, which would explain some of the failures; but we also knew that there are different varieties of puerperal sepsis, and this would account for the fact that some observers had reported successes and others failures. He was hopeful that in the near future we would have at our disposal the particular variety of serum which would effectually combat the variety of puerperal sepsis found in the given case. Reasoning from our experience with diphtheria antitoxin, it was also fair to assume that many failures with the serum and ointment were attributable to their having been used too late. He did not see how it was possible to compare the surgical treatment of puerperal sepsis with the surgical treatment of other forms of sepsis, because the conditions were so dissimilar.

The Desert Climate for Consumptives.—R. M. Phelps summarizes the main features of this form of climatic treatment as living on unirrigated ground, living in a tent, and living outside the limits of any city. He is a most enthusiastic advocate of tenting, to which should be added directions as to adjusted exercises, or better, rest and exercise, and admonition to guard against the changes from sun to shade, from night to day, from calm to rain. These changes are common to all dry climates, and most serious in the two or three winter months. Some complaints arise from patients who are taking the "desert" treatment. They complain of dampness, of no effect from the climate, of catching cold, and of homesickness. The remedies for the latter are enumerated as an occupation to fill up the time, the presence of one's family, home life, and means enough to avoid financial worry. The majority cannot command all these elements.—*Northwestern Lancet*

Clinical Department.

POST-OPERATIVE HEMORRHAGE TWELVE HOURS AFTER VAGINAL HYSTERECTOMY; LAPAROTOMY UNDER COCAINE ANÆSTHESIA; HEMORRHAGE FROM MESOCÆCUM AND MESOAPPENDIX.

By JULIUS ROSENSTIRN,
SAN FRANCISCO, CAL.,
SURGEON TO MT. ZION HOSPITAL.

Mrs. L., aged forty-four years, born in Germany, married, presented herself on December 29 in the Mount Zion Hospital clinic. The family history was negative; menstruation appeared at fifteen and was normal as to time and quantity. She has been married six years, has never been pregnant, and has always been well until two years ago, when she commenced to suffer from a pain in the lumbar region, in the right side of the abdomen, and in the middle line below the umbilicus. Menstruation became irregular and most profuse, also very much prolonged, lasting at times throughout the month. Treatment in various clinics proved unsuccessful. The patient, who was of middle height and dark complexion, looked very anæmic. The temperature and pulse were normal, lungs and heart healthy. Percussion and palpation of the abdomen revealed nothing, excepting that above the symphysis a hard mass was felt on deep pressure. The external sexual organs appeared normal, and a vaginal inspection showed normal conditions, except a small polypus, the size of a strawberry, protruding from the os uteri. Bimanual examination under chloroform showed the womb enlarged to the size of a large fist, hard, with a big nodule on the anterior wall somewhat movable, and a mass in the right parametrium, evidently the right ovary, the size of a small orange; the left side was free; the womb was not freely movable. Very little pain was caused by careful examination. On account of menstruation the operation was deferred until January 11, 1900. A posterior vaginal incision was made into the pouch of Douglas. The peritoneum was opened, and about sixty grams of slightly sanguinolent liquid escaped. Digital exploration through the pouch of Douglas showed conditions about as outlined before. The mass in the right parametrium was the firmly adherent right ovary and tube reaching very far laterally. The vaginal circular incision then being completed, the womb was pulled down, bisected up to the internal os, and small cuneiform pieces were excised to diminish its size; and finally the large womb, studded with fibroids, the whole the size of a small cocoanut, was brought out. At this stage a large quantity, about 400 to 500 c.c. of dark, bloody, viscid liquid gushed out through the wound, apparently from the right side. The right cystic ovary and the tube were then freed from adhesions, a rather difficult task, and brought to view. A good many of the little cysts were torn in the attempt, but finally everything was detached and pulled into the vagina. The ovary was the size of a mandarin orange. The tube was enlarged to the size of a man's finger and filled with a dark viscid fluid. The usual two clamps were applied to the right broad ligament, and the ligament cut wombward to them. The appendages of the left side were inspected. They showed no grave pathological change and were left intact, except for a few pea-sized cysts which were cut open. The uterus was then separated in the same manner on the left side, the peritoneum was tightly whipped over the vaginal wall with medium-sized catgut, and a small tampon was left in the opening.

At 10 A.M., after the woman was placed in bed the temperature was 96.2°, pulse 62, strong and regular. At 9.30 P.M., after some severe spells of vomiting and retching, a rather sudden and abundant onset of oozing was observed, the pulse rose to 124 and grew weak and fluttering, while the temperature fell to 96.4°, and the breathing grew more rapid. About 10 P.M., a telephone message reached me, acquainting me with the patient's condition. I arrived at the hospital at 10.30, and after a hurried examination had the patient removed to the operating room. The pulse was by this time 160, very feeble and disappeared on the slightest pressure; the respiration was quick and superficial, the skin of an extreme pallor and covered with cold perspiration. A quick but thorough examination on the operating table, aided by the light of the electric reflector, showed that there was no hemorrhage from the cut surface, the clamps as well as the vaginoperitoneal sutures acted perfectly. After removal of the tampon the blood could be seen to issue from the right side of the abdominal cavity, but a more exact location could not be made. It was determined to open the abdomen under cocaine anæsthesia.

During this brief period of examination, a saline infusion of 1,250 c.c. had been given with no appreciable effect. With the kind assistance of my associate at the hospital, Dr. Levison, and Dr. Dinkelspiel, the interne, an incision from 2 cm. above the symphysis to the umbilicus was made, and a rapid search followed for the bleeding points. Fortunately, when the belly was opened, the intestines in the right iliac fossa appeared covered with blood; those in other parts seemed comparatively free. I consequently directed my efforts toward that region and was soon rewarded by finding the source of bleeding in torn adhesions on the lateral side of the mesocæcum and mesoappendix. In separating and removing the enlarged and adherent right ovary, I had torn these adhesions.

There had been no appreciable oozing until the violent attacks of vomiting started the hemorrhage, which had to be stopped at once. The pulse was imperceptible. I could not lose time with ligating the bleeding points, but tamponed tightly, after Mikulicz, and closed the abdomen by through and through silkworm sutures, with the exception of a small opening in the center for the ends of the Mikulicz tampon. Although, during this time, nearly 2,000 c.c. of saline infusion had been given, the pulse could be felt only at intervals, but not really counted. The oozing had stopped, the patient was placed in bed, strychnine $\frac{1}{30}$ gr. and digitalin $\frac{1}{50}$ gr. hypodermically were ordered every four hours. A nutritive enema of milk and whiskey was given in strong coffee with cream, taken by the mouth. Rectal feeding was continued until January 17, vomiting having been persistent. After it was discontinued, and nourishment by the mouth increased, bowels began to move freely; in fact, too freely; in ten hours patient had ten bowel movements.

On January 23 and 24 the bowel movements became normal, the vaginal wound was perfectly healed and united, covered with healthy granulations, the stitches were taken out from the abdomen, and wound healed by primary intention.

On January 25, the patient commenced to lose urine from the vagina. An examination showed a fistulous opening the size of the head of a match, posteriorly in left side of vaginal roof. The urine spurted out at intervals of about a minute, during which the fistula was dry. Colored liquids injected into the bladder did not run out through the fistula. Cystoscopic examination showed no urine coming from the left ureteral opening. Attempts at catheterization of the left ureter did not succeed. No

symptoms of retention of urine having been observed previously, I concluded that only a partial lesion of the ureteral wall had occurred, which, in time, would be apt to heal by granulation. I elevated the foot of the bed and had the patient lie on her stomach as much as possible. Already on January 30 the quantity of urine lost through vagina had considerably decreased, although a recurrence of diarrhœa sadly interfered with the permanency of the ventral posture. On February 5 hardly any urine was lost involuntarily; she lost no urine on February 6, and the fistula has remained closed since that time.

This cause of a post-operative hemorrhage after vaginal hysterectomy, has not been mentioned in the literature of this operation, so far as I can discover. One can hardly believe that similar occurrences, of a lesser gravity perhaps, should not have been observed by many operators. The proximity of the right appendages to the cæcum and vermiform process must often permit extension of the inflammatory process from one to the other. The right ovary is suspended between the ligamentum suspensorium ovarii on the outer and the ligamentum proprium ovarii on the inner side.* The latter extends from the ovary to the uterus, the former from the ovary to the cæcum and processus vermiformis. It is amply provided with lymphatics and blood-vessels, communicating with and extending to those of the mesoappendix and mesocæcum. Here lies the bridge for travel of inflammatory and infectious processes from one to the other, involving finally both in such close embrace that it becomes impossible at times to determine before the operation which of the organs has been the primary seat of affection. In the case just reported vascular adhesions had formed between the peritoneal covering of the right ovary and tube, the anterior surface of the suspensory ligament and the outer surface of the mesocæcum and mesoappendix, the growth in the adherent ovary having crowded the cæcum backward and inward. These adhesions were torn during the freeing and removal of the right appendages on their mesocæcal side.

For some unexplained reason, no appreciable bleeding occurred during and after the operation until nearly twelve hours after its completion. The hemorrhage occurring subsequently to prolonged, very severe retching and vomiting, possibly the consequent removal of an occluding thrombus may have started it. It cannot be denied that an operation by the abdominal route would have saved all this trouble, and in all cases of vaginal hysterectomy, when the appendages are firmly adherent and require a certain degree of force to be liberated, I shall certainly not hesitate to add a cœliotomy and free all adhesions under full control of the eye, when provision can be made against accidents.

PRESBYOPIA OF CIVILIZATION

BY NORBURNE B. JENKINS, M.D.,
CHICAGO

IN some parts of civilization the habits and customs of life weaken, injure, and prematurely age the eyes. The focusing muscle may never develop or may prematurely lose its strength. The crystalline lens may not be normal of elasticity. The optic nerve and its retina may not have keen power of receiving impressions. In Boston, New York, and Chicago glasses are needed for failing eyesight earlier than in the mountains, plains, and farming country of the South and Middle West.

After correcting with distant vision tests the total imperfections of the size and shape of the eyeballs, in Boston most people about forty years of age need magnifying added for reading; in New York, most after forty-two need such, and in Chicago at about forty-five, while in the mountains, plains, and farming country of the South and Middle West such help is not needed until about the fiftieth year.

Indoor life, air starvation, insufficient fresh meat, long hours in close schools, lack of play, vegetarianism, unsanitary houses and clothes, non-use of the eyes for long distances, lack of green fields and forests, short, dangerous distances of the schoolroom powerful artificial lights, unnatural surroundings of overprotected and finicky city life—all tend to ruin the eyes and unfit the population for military duty.

INFUSORIAL DIARRHŒA

BY M. HARTWIG, M.D.
BUFFALO, N. Y.

THE other day I reported to the Buffalo Academy of Medicine a case of chronic diarrhœa in a woman sixty years of age, where blood and pus as well as mucus were absent; but there was an enormous quantity of very lively infusoria. They were oval, or, rather, egg-shaped, of about the size of white blood corpuscles, and had one or two flagella on the narrower end. The patient was cured by large injections of one-half to one tablespoonful of tannin in one and a half quarts of water, after the diarrhœa had lasted three weeks, and resisted bismuth subgall. gr. v., with duotal gr. v. and opium gr. $\frac{1}{12}$, every four hours, and, of course, careful diet. Whether the infusoria had been the cause of the diarrhœa is impossible to decide, but their great number (five to eight in one field, immersion one-twelfth) speak for such an explanation. The organism did not take the Loeffler alkaline methylene stain. It seems not to have been observed as yet. Hemmeter thought it might have been the parametrium or Balantidium coli, but this has no flagella, but cilia all over the surface, and shows considerable contents, while the infusorium in this case looked almost like glass. As far as I could see, it resembled the Trichomonas vaginalis. We could call it ovomonas flagellatum coli.

AN EPHEMERAL ATTACK OF HENOCH'S PURPURA.

BY CHARLES H. RICHARDSON, M.D.
NEW YORK

THE following case, on account of the rapidity of its course, seems to be worthy of report. The patient, a rather delicate girl of eleven years, was seized with vomiting of blood, tenderness of the abdomen, pain in the fingers and wrists, general malaise, and a temperature of 102°. During the night she had three or four stools consisting mainly of blood. On the following morning, when I again saw her, the pain in the wrists had increased, and there was also pain in the ankle joints. The legs now exhibited numerous purpuric spots, and the prostration was quite severe. During the day, no further gastric or intestinal hemorrhage occurred, the temperature subsided, the pain in the joints diminished and disappeared. On the following morning, only the pigmented spots remained. There was no history of previous attacks, and as the patient returned to her home in the West, I have been unable to learn if subsequent ones

Therapeutic Hints.

Ethereal Soap Solution.—

℞ Acidi oleici 7ss.
Spir. vini rect 7ss.
Liq. ammon. fort. q. s.
Ether methylat. ʒij.

Mix the first two and add enough of the ammonia to neutralize. Petroleum spirits of benzene can be substituted for the methylated ether.

—Herbert Snively.

Suppurative Otitis Media.—

℞ Formaldehyde gtt. v.
Alcohol (95%) ʒij.
Water ʒij.

M. S. Instil with an ear-dropper sufficient to fill the middle ear and external canal. In acute cases two or three drops to an ounce of water is strong enough.

—Wake.

Simple Chronic Bronchitis in Children.—

℞ Sodii sulphat 15 gm.
Antomonii tartrat 0.05 cg.
Syr. simplicis 10 gm.
Aq. destil. 120 gm.

M. S. To be taken in four or five doses.

—Comby.

Lemonade Powder.—

For use in infectious diseases with fever.

℞ Sodii bicarbonat 0.5 gm.
Pulv. acidi tartarici 0.6 gm.
Sacch. alb. 1.25 gm.
Olei limonis gtt. xij

Catarrhal Conjunctivitis.—

℞ Ammon. chloridi 0.67 cg.
Zinci sulphat 0.15 cg.
Camphoræ
Croci āā 0.01 g.
Aq. destil. 15 gm.

M. S. To instil into eye.

—Terrier.

Gastric Fermentation.—Massage and "Zimmer Gymnastik" after the method of Schreber lead to material improvement. The nervous symptoms, often in the ascendancy, can be relieved by giving the patient agreeable occupation. Make the heart light by keeping the brain active. For well-selected cases, where fermentation is excessive, belching of gas annoying, constipation depressing, with pressure symptoms, the following formula is suggested:

℞ Strychniæ sulphatis 0.00 gm.
Ext. belladonnæ fld. 0.6 gm.
Aquæ lauri ceras. 1.50 0 gm.
Tinct. gelsemii 12.0 gm.
Aquæ puræ ad 120.0 gm.

S. Teaspoonful before each meal.

—Elsner, *International Med. Magazine*, July.

Mercurial Stomatitis.

Cauterize the plaques with

℞ Argenti nitratis 1 gm.
Tinct. eucalypti 5 gm.
Aquæ 25 gm.

—Vaucaire.

Enuresis.—Give a saturated solution of boric acid in combination with salol.

—P. F. Barbour.

Hydrotherapeutic Don'ts.—Don't bathe with cold water to reduce temperature, but to refresh the fever-stricken patient.

Don't permit cyanosis or chattering of teeth to stop.

Don't stop bathing because patient complains of chilliness, unless the teeth chatter.

Don't raise bath temperature on the latter account; shorten bath and increase friction.

Don't neglect friction during every cold procedure; it prevents chilling.

Don't disregard the well-ascertained fact that the Brand bath (of 65° to 70° F. every three hours when awake, with active friction) is the ideal bath for typhoid fever early.

Don't use the Brand bath in a bathroom.

Don't give up cold bathing because the ideal bath is not obtainable; other procedures are useful.

Don't use the ice coil to the abdomen; it has no refreshing effect and renders the skin beneath it cyanotic.

Don't lose sight of the fact that the chief aim of all cold procedures is reaction.—Dr. L. Baruch, *The Medical Gazette*, September 15, 1901.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 7, 1901:

	Cases	Deaths
Measles	547	5
Diphtheria and croup	333	18
Scarlet fever	106	2
Smallpox	55	2
Chickenpox	47	..
Tuberculosis	217	124
Typhoid fever	6	..
Cerebrospinal meningitis	..	..

Cocaine Eating Among the Natives of Bengal.—The habit of cocaine eating seems to have spread extensively among the natives of Bengal. It is sold in small paper packets, containing half a grain or one grain, which can be obtained for half an anna, or one anna respectively. It is impossible to say how much is consumed by any one individual, but several grains a day have been confessed to. The sense of feeling well is followed by depression, but the habit appears to be peculiarly seductive, and once commenced is with the greatest difficulty abandoned. A blackening of the teeth is said to be caused by cocaine eating, and the blackening is thought to be characteristic. It is said to be most marked in the lower teeth, and on the inner or posterior surface, and to be quite different from dirt or the staining of tobacco. The general symptoms are those of cachexia with a sallow look, sunken eyes, and emaciation.—*Lancet.*

Kidney Disorders Usually Included Among the Forms of Bright's Disease.—(I) Acute nephritis or acute Bright's disease (sub-variety, the nephritis of pregnancy). Under chronic Bright's disease the following forms are usually recognized:

(II) Chronic parenchymatous nephritis (sub-variety, chronic parenchymatous hemorrhagic nephritis).

(III) Chronic interstitial nephritis: (a) Contracted white kidney (secondary cirrhotic kidney); (b) primary cirrhotic kidney; (c) Arterio-sclerotic kidney. Some authors include amyloid kidney among the forms of Bright's disease, but this is unusual; the pathological lesions are, of course, of a different nature from those of Bright's disease.

The primary cirrhotic kidney and the arterio-sclerotic kidney are usually included among the forms of Bright's disease, though some authors would exclude them.—Dr. R. T. Williamson.

Plague Statistics.—Bombay.—Thus, the plague in Bombay made 46,000 victims in three years and a quarter, and it increased the general death rate by nearly 52 per cent.

CASES OF AND DEATHS FROM PLAGUE IN CITY OF BOMBAY.

YEAR	PLAGUE CASES REPORTED	PLAGUE DEATHS CERTIFIED	CASE-MORTALITY PER CT.
1896	2,550	1,801	71

1898	10,863	18,160	..
1899	10,484	15,830	..
Totals	33,860	46,023	85.4

The Use of Drugs in Phthisis.—To admit that there is no drug endowed with specific virtue in phthisis is not to admit that drugs are never useful. For the fever and that the open air will reduce fever, will prevent sweats—will, either due to fever or debility—will promote appetite, and will calm and fortify the circulation. But it is not to be forgotten that during liberal feeding, gentle laxatives and especially an occasional mild mercurial alterative prove valuable; that a drop of an arsenical solution may settle an irritable stomach, a few drops of strychnine may cause

up a slack one, and so on; but I have no faith in courses of drugs, whether antidotal, tonic, or topical, save, of course, in laryngeal cases, which, as the part can be got at, are to be treated locally from the first.—Dr Clifford Allbutt.

Thermal Death Point of Tubercle Bacillus.—Dr. R. T. Hewlett has made some experiments on the thermal death point of the tubercle bacillus. His conclusions are that (1) A non-virulent laboratory culture, a temperature of 60° C. acting for ten minutes, is sufficient to destroy the infective properties of tubercle sputum in five out of six instances. (2) Tuberculous milk, heated to 62° C. for thirty minutes, lost its infective power. (3) Tuberculous milk heated to 68° C. for twenty minutes in the Allenbury pasteurizer lost its infective power. (4) In all probability, pasteurization, in which the milk is retained at a temperature above 65° C. for not less than twenty minutes, is efficient, especially if no film is formed.

Habits of Mosquitos.—Observations made by the members of the malaria expedition of the Liverpool School of Tropical Medicine to Nigeria revealed the following facts with regard to the habits of mosquitos, which largely confirmed the results of previous researches:

Anopheles were found in shallow surface puddles, in collections of water, in native dug-out canoes, in claypits and wells, in ditches at the side of roads, in marshy ground in the neighborhood of springs, and in the hollows left by the subsidence of rivers in the dry season. The investigations in Nigeria also confirmed the view that Anopheles will not breed at any distance from human habitation.

The First Thermometer.—The first sealed thermometer was made sometime prior to 1654 by Ferdinand the Second, Grand Duke of Tuscany; he filled the bulb and part of the tube with alcohol, and then sealed the tube by melting the glass tip. There appears to be considerable doubt as to who first employed mercury as the termometric liquid; the Academia del Cimento used such an instrument in 1657, and they were known in Paris in 1659. Fahrenheit, however, appears to have been the first to construct, in 1714, mercury thermometers having trustworthy scales. The use of the boiling point of water was suggested by Carlo Renaldini in 1694.—*The Engineer.*

Tetanus from Injecting Gelatine.—The London Correspondent to the *Therapeutic Gazette* says: "A large London hospital has recently been unfortunate in suffering two deaths from "tetanus" after subcutaneous injections of gelatine for the cure of aneurysms. The evidence given in the coroner's court told one nothing of grounds upon which death was attributed to tetanus. It is hardly probable that any article contaminated by the bacillus can have been used in the preparation or administration of the solution. Moreover, similar symptoms have been recorded in other cases. A writer in the *British Medical Journal* suggests that the symptoms were due to formation of capillary thrombi in the nervous system leading to fatal convulsions.

Unhealthful Clothing.—Among all the murderous forms of dress, underclothing takes the lead, and of this cotton and linen garments are the chief offenders. The cotton shirt especially is a vicious thing. When it has become damp from perspiration, it is virtually air-tight, and a draught striking it converts it into a cold storage lining, which could not be better designed for pneumonia. A garment of genuine wool takes up the perspiration, and the warmth of the body under it evaporates the moisture.—*Chicago Tribune.*

Effect of Rainy Season on Malaria.—It is well known that mosquitos cannot live in water, and therefore it is not surprising to find that the number of cases of malarial fever vary considerably according to the season of the year, and that the greatest number of cases occur at the onset of the rainy season, when mosquitos are particularly abundant.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended December 7, 1901:

THE CURE OF CHRONIC BRIGHT'S DISEASE BY OPERATION.

BY GEORGE M. EDEBOHLS, A.M., M.D.

PROFESSOR OF THE DISEASES OF WOMEN, AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO ST. FRANCIS' HOSPITAL, NEW YORK; CONSULTING GYNECOLOGIST TO ST. JOHN'S HOSPITAL YONKERS, N. Y., AND TO NYACK HOSPITAL, NYACK, N. Y.

THE proposition to treat chronic Bright's disease by operation was first made by the author in a paper entitled "Chronic Nephritis Affecting a Movable Kidney as an Indication for Nephropexy," published in the *Medical News* of April 22, 1899. The proposition was based upon the favorable results obtained in four out of six cases in which the writer had performed nephropexy for the purpose of anchoring a movable kidney in the presence of well-marked chronic Bright's disease. In five of these six cases nephropexy was undertaken without any idea of favorably influencing the chronic nephritis known to exist; the indication for operation being given solely by the existence, in an aggravated degree, of the usual symptoms due to mobility of the kidney or kidneys. The effects of nephropexy upon the coexisting chronic Bright's disease, whatever they might prove to be, were simply hazarded in view of the necessity of relieving the patient of a number of intolerable symptoms.

My first case was operated upon as long ago as November 29, 1892; my fifth, upon April 1, 1897. The complete and permanent disappearance of albumin and casts from the urine, and the restoration to perfect and enduring health of three of the five patients, led me to advise bilateral nephropexy in my sixth patient, a sufferer from chronic Bright's disease complicated with movable kidneys, mainly with the object of favorably influencing the chronic nephritis.

This operation, performed on January 10, 1898, constitutes the first operation ever undertaken upon the kidneys with the deliberate purpose of curing chronic Bright's disease, and in so far marks a period in the history of the affection. As a result of the operation the patient was radically cured of her chronic Bright's disease, and remains so to this day.

Encouraged by the permanence of the cures of chronic nephritis in these earlier cases, I have, during recent years, performed nephropexy by preference upon patients suffering from chronic Bright's disease. This may account for the fact that among the 191 patients upon whom I have performed nephropexy, there were no less than sixteen sufferers from chronic nephritis. The results, as will be detailed further on, proved gratifying beyond all expectation. As none of the patients after operation received any further treatment for their chronic Bright's disease, the conclusion became inevitable that the cures and improvement obtained with practical uniformity must be ascribed to the operation itself.

Gradually the idea dawned upon me that surgical procedures which led to a cure of chronic nephritis in kidneys that were movable, would be even more likely to prove curative when applied to kidneys not suffering from displacement. For a while the conception, that the cure of the chronic Bright's disease was due to the correction of the displacement of the kidney by nephropexy, stood in the way of the development of the idea. It was not until three secondary operations upon kidneys which had been anchored some time previously, demonstrated to me what I now believe to be the essential conditions underlying the cure of chronic Bright's disease by operation, that I saw my way clearly in the matter.

The result of this study and interpretation of my accumulating experience was embodied in the formal proposition, advanced in the MEDICAL RECORD of May 4, 1901, page 691, to treat all cases of chronic Bright's disease surgically. The principles underlying the cure of chronic nephritis by operation, and the method of operation to be followed in carrying these principles into effect, were also indicated. A promise was likewise implied to discuss the subject in a fuller and more formal manner as soon as certain investigations then pending were completed. In fulfillment of this promise the present paper is presented.

I will first outline, in tabular form, the essential points in the histories of all the cases of chronic Bright's disease which I have treated by operation, including, for the sake of completeness, the six cases already published. The analysis of this table will serve as a basis for some deductions and general considerations to follow.

On December 3, 1901, I performed decapsulation of both kidneys on a woman of forty-three, referred to me from the First Medical Division of St. Francis Hospital, by Dr. Fritz Schwyzer, Attending Physician. A brother of the patient died of chronic Bright's disease. Patient herself seems to have suffered from chronic Bright's disease and cardiac derangement for the past two years. At the time of operation she had an extreme hypertrophy of the heart, with a mitral systolic and a mitral regurgitant murmur. Operation disclosed far advanced chronic interstitial nephritis, both kidneys being granular and shrunk to half their normal size. At the present writing, December 10, 1901, patient's general condition and the improvement in the work performed by the kidneys are both perfectly satisfactory. On account of the short period of observation I have not included the case in the table.

All of my eighteen patients were women, whose ages, varying between nineteen and forty-five years, averaged thirty and one-half years.

Cases of chronic Bright's disease only are included in the list. I have operated a few times upon kidneys affected with acute Bright's disease, and quite a number of times upon kidneys the seat of well-marked congestion, either acute or chronic, and, with one exception, always with good results. Such operations and such results, however, prove little or nothing, the tendency of acute nephritis, in the vast majority of cases, being toward spontaneous resolution

TABLE I.

AUTHOR'S CASES OF CHRONIC BRIGHT'S DISEASE TREATED BY OPERATION.

NO.	NAME.	AGE.	CONDITION OF KIDNEYS AT OPERATION.	DATE AND NATURE OF OPERATION.	REMARKS AND RESULT.
1	Miss A. B. Hospital patient.	18	Right chronic interstitial nephritis.	29-XI-1902 — Right nephropexy.	Chronic Bright's disease, to my knowledge, for a year prior to operation. Urine became normal two months after operation, and remained permanently normal to date of last examination, 18-IV-1903, at which date patient was in the enjoyment of perfect health.
2	Mrs. G. H. Hospital patient.	39	Right and left chronic interstitial nephritis.	10-III-1903 — Bilateral nephropexy.	Bright's disease recognized shortly prior to operation. Previous duration unknown. On discharge of patient, six weeks after operation, Bright's disease unimproved. Patient not seen since leaving hospital.
3	Mrs. M. M. Dr. R. G. Wiener.	28	Right chronic diffuse nephritis, with formation of large cyst. Left kidney, probably, also diseased.	11-V-1903 — Incision of right kidney and evacuation of contents of cyst. Suture of kidney wound. Right nephropexy.	Chronic Bright's disease, to Dr. Wiener's personal knowledge of several years' standing before operation, persisted after operation. Dr. Wiener writes me under date of 7-XI-1903: "Mrs. M. M. died last May after an abdominal hysterectomy done by Dr. A. She had her left kidney removed about five years ago by Dr. B." This patient lived for eight years after my operation, the last five with only one kidney, the one originally operated upon. At the end of that time she still had nephritis, but not in sufficient degree, apparently, to contraindicate the serious operation of which she died.
4	Miss L. G. Dr. B. R. Morrow.	28	Left chronic interstitial nephritis. Right kidney healthy.	12-I-1896 — Bilateral nephropexy.	Bright's disease was recognized shortly prior to operation, and disappeared permanently four months after operation. 21-XI-1901: Urine normal and patient in perfect health.
5	Mrs. M. F. Dr. P. J. Lynch.	42	Right chronic interstitial nephritis.	3-IV-1897 — Right nephropexy.	Patient under constant treatment for chronic Bright's disease during six years preceding operation. Urine became normal one year after operation, and has so remained. 30-X-1901: Urine normal; patient in perfect health.
6	Miss S. O. Dr. A. Strong.	20	Left chronic interstitial nephritis. Right kidney healthy.	12-I-1898 — Bilateral nephropexy.	Bright's disease was accidentally discovered a short time before operation. Urine became normal one month after operation, and has so remained. 24-X-1901: Urine normal; patient perfectly well. This is the first patient operated upon for the express and deliberate purpose of curing chronic Bright's disease.
7	Mrs. F. B. Dr. J. M. Egan.	28	Right and left chronic interstitial nephritis.	24-I-1899 — Bilateral nephropexy.	Chronic Bright's disease recognized several months prior to operation, duration prior to recognition uncertain. Urine became permanently normal five months after operation. 26-X-1901: Urine normal; patient enjoying good health.
8	A. Van W. Dr. B. R. Morrow.	45	Left chronic interstitial nephritis. Right kidney healthy.	5-III-1900 — Bilateral nephropexy.	Bright's disease discovered shortly prior to operation. Urine became permanently normal four months after operation. 25-X-1901: Urine normal except for presence of uric acid crystals in large numbers. Patient gouty, but otherwise well.
9	Mrs. C. G. Hospital patient.	42	Right chronic interstitial nephritis. Left kidney?	21-V-1900 — Right nephropexy.	Chronic Bright's disease recognized five months prior to operation. Albumin and casts had almost disappeared from urine on discharge of patient, five weeks after operation. Since then no trace of her can be found.
10	Mrs. L. J. Hospital patient.	26	Right chronic interstitial nephritis. Left kidney healthy.	12-V-1900 — Bilateral nephropexy.	Chronic Bright's disease first recognized six months prior to operation. No change four weeks after operation, when patient left hospital, after which all trace of her was lost.
11	Mrs. S. G. Private patient.	28	Right chronic interstitial nephritis. Left kidney healthy.	4-XI-1899 — Bilateral nephropexy.	Duration of Bright's disease prior to operation unknown. Four weeks after operation no change in urine. Patient then lost sight of. Died after an operation for ruptured tubal pregnancy, exactly one year after nephropexy. Drs. S. J. Meltzer and J. Brettauer, who attended her in her last illness, inform me that there was then no chronic Bright's disease, the urine being perfectly normal.
12	Miss R. H. Dr. G. F. Blauvelt, Nyack, N. Y.	22	Left chronic interstitial nephritis and acute perinephritis. Right kidney normal.	5-XI-1902 — Bilateral nephropexy.	Bright's disease accidentally discovered just prior to operation. Urine became permanently normal two months after operation. 18-XI-1903: Urine perfectly normal, and patient enjoying good health.
13	Miss M. D. Hospital patient.	19	Right and left chronic interstitial nephritis.	22-XI-1902 — Right nephropexy. 10-IV-1903 — Left nephropexy.	Bright's disease was recognized just prior to right nephropexy, and persisted until left nephropexy, five months after which it entirely disappeared. 22-X-1903: Urine normal.
14	Mrs. L. K. Dr. H. Ruhl.	23	Advanced right and left chronic diffuse nephritis.	5-IV-1901 — Bilateral nephropexy.	Mother of patient died at forty, and her only sister at twenty-seven, both of chronic Bright's disease. Her father and a younger brother are ill with chronic Bright's disease. Patient herself has been under treatment for Bright's for over a year. Dr. Ruhl advised operation upon both kidneys for the purpose of curing her of chronic Bright's disease. 20-X-1901: Decided improvement in urinalysis findings. Albumin in urine one-third the amount before operation; casts less numerous; patient improving in other respects.
15	Mrs. R. K. Dr. H. Ruhl.	31	Right and left chronic interstitial nephritis.	15-IV-1901 — Bilateral nephropexy.	Bright's disease recognized shortly before operation. 4-XI-1901: Urine normal except for low specific gravity.
16	Miss I. H. Dr. G. H. McGuire.	23	Right and left chronic diffuse nephritis, with extensive perinephritis on left side.	7-V-1901 — Bilateral nephropexy.	Chronic Bright's disease accidentally discovered one month prior to operation. A piece of kidney tissue removed at operation showed advanced chronic nephritis on microscopical examination by Professor H. T. Brooks. Improvement began soon after operation, and on 6-XI-1901, Professor Brooks reports that "urine shows only very slight evidence of renal disturbance."
17	Mrs. M. S. Dr. T. W. Vardon, Guelph, Ont. Canada.	33	Right and left chronic parenchymatous nephritis.	22-X-1903 — Ex[illegible] proper [illegible]	Chronic Bright's disease for five years preceding operation. Operation advised by Dr. H. H. Witt, Guelph, Ont. Canada, in consultation with Dr. T. W. Vardon, patient's physician. Patient, at time of operation, practically moribund. Case detailed in body of paper.
18	Mrs. C. B. Dr. A. O. Bristol, Spencer Valley, N. Y.	30	Right and left chronic parenchymatous nephritis with multiple septic foci.	9-VIII-1901 — Right [illegible] for [illegible] 12-XI-1901 — Excision of [illegible] proper of [illegible]	Bright's disease first noted during last pregnancy; birth of child 1-II-1901. Septic [illegible] following uterine fibroid, continuous [illegible] 12-III-1901, when the septic uterus [illegible] sloughs, and a suppurating intraligamentous uterine fibroid were removed by abdominal panhysterectomy. Subsequent infection of right kidney necessitated excision of that [illegible] 9-VIII-1901. Persistence of chronic Bright's disease in [illegible] 12-XI-1901, necessitated excision of the renal capsule proper, 16-XI-1901. Details of case in body of paper.

or cure. It is only when Bright's disease has become chronic that it is considered incurable.

The classification of chronic Bright's disease according to the pathological conditions found in the kidney varies greatly with different authorities. Parenchymatous nephritis, or inflammation of the secreting structures, the tubules and glomeruli, of the kidney, and interstitial nephritis, or inflammation of the renal connective tissue, form the two basic pathological entities upon which all agree. Confusion, in the further elaboration of the subject, arises chiefly from the fact that neither of the two conditions ever exists absolutely by itself; *i. e.*, one variety of inflammation is never present without some admixture, greater or less, of the other The variations in degree of each, in which parenchymatous and interstitial nephritis are found associated, are almost infinite, and explain the luxuriant abundance of classifications.

A practical division or classification, in the writer's opinion, is to designate as interstitial nephritis those cases in which the gross evidences of inflammation of the connective tissue of the kidney predominate; as parenchymatous nephritis, those in which involvement of the secretory apparatus forms the salient feature; and as diffuse nephritis, those inflammations of the kidney characterized by implication, in fairly equal degree, of both the parenchyma and the connective tissue of the organ. The diagnosis of these three varieties of chronic nephritis upon the living kidney, when exposed during operation, is easy after some experience, pathological changes being more readily appreciated with the blood circulating through the organ than they are after death.

Of the eighteen patients with chronic Bright's disease operated upon by the writer, five had right chronic interstitial nephritis; four had left chronic interstitial nephritis; four had right and left chronic interstitial nephritis; two had right and left chronic parenchymatous nephritis; three had right and left chronic diffuse nephritis.

In fourteen of the eighteen cases both kidneys were operated upon; in twelve instances at one sitting, and twice at two sittings. In four patients operation was performed on one kidney only, in every instance the right.

Of the four patients whose right kidney alone was operated upon, two have recovered complete and lasting health. It may be taken for granted, therefore, that their left kidneys were at the time of operation, as they are now, in perfect health. A third patient upon whom I performed right nephropexy disappeared from observation soon after operation; the condition of her left kidney must remain a matter of conjecture. The fourth patient, finally, whose diseased right kidney I operated upon, had her left kidney removed by another surgeon within three years after my operation on the right. In this case the left kidney was presumably diseased at the time I operated upon the right.

Embodying these conclusions with the statements contained in Table I, we find that the left kidney alone was affected by chronic Bright's disease in four cases, the right alone in four cases, and both kidneys in nine cases, while in one case the unilateral or bilateral nature of the disease remains undetermined. In other words, the chronic nephritis affected both organs in nine cases, and one kidney only in eight cases, one case remaining doubtful.

In six of the eight cases in which chronic Bright's disease is recorded as unilateral, the healthy condition of the other kidney was verified at operation, when both kidneys were brought out of the wound for careful and critical examination. It cannot be denied that, in some instances at least, microscopical examination of a kidney classed as healthy might have revealed evidences of incipient changes of an inflammatory character; to the unaided sight, however, and to the touch, the organ was healthy.

The fact that chronic Bright's disease may be unilateral in one-half, or nearly one-half, of a series of eighteen cases may come as a matter of surprise to many of my readers, as, indeed, it proved a revelation to the writer. The fact, however, well explains the chronic course of many cases of Bright's disease, and the comparatively little disturbance of health the disease sometimes occasions. The healthy kidney simply performs the eliminative work of both kidneys, and the toxæmic symptoms of uræmia are not manifested. In this regard, patients with Bright's disease affecting one kidney only are on a par with patients whose one kidney has been removed. Gradually, however, but none the less surely, in patients with unilateral Bright's disease, the steady loss of albumin through the affected kidney tells upon and undermines the general health, and leads, although in many cases only after the lapse of years, to a fatal issue. Probably, also, toward the end, the other kidney generally becomes involved, thus explaining the very great preponderance of bilateral over unilateral chronic Bright's disease as found in the dead house.

The diagnosis of chronic Bright's disease in the above eighteen cases was based upon the previous history of the patient, upon the chemical and microscopical examination of the urine, and, lastly, upon the critical test of actual inspection and palpation of the kidney at the time of operation. This evidence was supplemented in two cases by microscopical examination of a small piece of kidney tissue removed at operation.

In nine of the eighteen cases the existence of chronic Bright's disease was discovered on examination of the urine but a short time before operation, just as the first intimation of kidney disease often received by a man who considers himself in perfect health is the rejection of his application for a life-insurance policy, or for additional insurance in a company which at one time had considered him a good risk. Closer investigation of the histories of these nine patients, however, always revealed the previous existence of some indications, more or less pronounced in different cases, of deranged function of the kidneys. The other nine patients were fully aware of the existence of chronic Bright's disease in their persons for periods varying from several months to over six years preceding operation. In their cases the well-known severer symptoms of blood deterioration, dropsy, and uræmia were present in varying degrees and combination. The periods above given indicate the time elapsed between the first discovery of albumin and casts in the urine and the date of operation; how long chronic Bright's disease existed in each case before it was revealed by urinary examination, it is, of course, impossible to say.

The urine examinations, either establishing or confirming the diagnosis of chronic Bright's disease prior to operation, were, in the last fifteen of my eighteen cases, all personally made by Dr. Henry T. Brooks, Professor of Pathology in the New York Post-Graduate Medical School and Hospital. In a number of these fifteen patients the diagnosis had already been reached, after examination of the urine, by the patient's family physician. I preferred, however, to have the diagnosis verified and confirmed, in each instance, by one or several examinations of the urine made by such an unquestioned authority as Professor Brooks. My first three patients were operated upon prior to my acquaintance with the

latter gentleman. In my second patient, Dr. R. S. Wiener, the patient's physician, stands as sponsor for the urinalysis diagnosis of chronic Bright's disease; in my first and third cases the urinary examinations preceding operation were made by my house surgeon and by myself.

The evidences of chronic Bright's disease, as revealed by operation, clinched the diagnosis beyond peradventure in all of the cases. They were, in each instance, so positive and pronounced as to leave no room for doubt. The kidney, in all of my operations but one, was invariably delivered upon the skin of the back for examination and operation. In the one exception the right kidney was so delivered, but it was found impossible to deliver the left kidney, operation upon which was performed in the depths of the wound. This delivery of the kidney enabled me to demonstrate to all witnesses of each operation the visible changes produced by chronic Bright's disease in the particular kidney under operation—the adherent capsule, nodulation, granular condition of the subcapsular surface, shrinking, unequal contraction, and occasional cyst formation of chronic interstitial nephritis; the enlargement, cloudy swelling, mottling, and discolorations due to circulatory and degenerative changes, of chronic parenchymatous nephritis; the thickening, general or localized, of the capsule proper of the kidney, and the secondary inflammatory changes in the perirenal fat, common to both varieties of chronic Bright's disease. The variations in the density and hardness of the kidney substance, often varying widely in different parts of the same organ, could, for obvious reasons connected with asepsis, be appreciated only by myself and my assistant at the operation. With a personal experience of more than three hundred kidney operations available for comparison, I now find no difficulty in promptly determining, by inspection and palpation, whether a given living kidney before me for operation is, or is not, affected with chronic Bright's disease. It is for this reason, probably, that in only one instance have I felt myself justified in excising a small bit of kidney tissue at operation for the purpose of microscopical examination. The justifiability of deliberately depriving a patient, except under very exceptional and urgent indications, of even the minutest part of such an important excretory organ as the kidney, knowing that the defect can be made good only by compensatory hypertrophy, never by new formation of kidney tissue, is, to my mind, a subject of grave doubt. In the one instance referred to, the right kidney, as it lay before me at operation, delivered and stripped of its capsule proper, presented over its entire surface such an even and regular granular condition that a diffuse tuberculosis was suspected, which suspicion, if verified, would, of course, call for excision of the diseased organ. A minute piece of the kidney substance was excised and forthwith taken to Dr. Brooks' laboratory. The right kidney was then replaced in the body, and the left kidney, which showed clearly the evidences of chronic Bright's disease, was operated upon, while Professor Brooks made examination of frozen sections of the piece of right kidney sent him. In fifteen minutes the report came from Dr. Brooks: "Chronic interstitial nephritis; no tuberculosis," whereupon nephropexy upon both kidneys was completed. In one other patient, while performing total excision of the renal capsule proper, a small bit of kidney tissue came away with the capsule. Examination of this tissue was made by Professor Brooks, who found "chronic diffuse nephritis, with foci of sepsis in some of the tubules."

Right nephropexy was performed upon four, and bilateral nephropexy upon twelve, of my eighteen patients. Extensive denudation of the kidney cortex, by stripping off the capsule proper, so as to lay bare about one-half of the surface of the kidney, was a feature of all these nephropexies. This fact, in my opinion, has a distinct bearing upon the results, as will be explained further on. In three or four instances renal cysts of various sizes were punctured and evacuated prior to anchoring the kidney.

A detailed account of the operation of nephropexy, as I now perform it, will appear in the *Annals of Surgery*, February, 1902.

Upon my last two patients, I performed total excision of the renal capsule proper with the sole and specific object of bringing about a cure of chronic Bright's disease. In one of the two patients both kidneys were operated upon at the same sitting. The other patient had but one kidney, as I had been compelled to remove the septic right kidney some months prior to performing excision of the capsule proper of the left kidney.

Excision of the renal capsule proper is performed as follows: The patient is placed prone upon the table, with the author's kidney air-cushion underlying and supporting the abdomen. Both kidneys are thus rendered accessible to operation without the necessity of changing the patient's position. An incision is carried from the twelfth rib to the crest of the ilium along the outer margin of the erector spinæ, without opening the sheath of that muscle. The fibers of the latissimus dorsi muscle are bluntly separated in the direction of their course, without cutting. The iliohypogastric nerve is sought for and drawn to one side or other, out of the way of harm. Division of the transversalis fascia exposes the perirenal fat. This is divided over the convexity of the kidney until the capsule proper is reached. The fatty capsule is now bluntly separated everywhere from the capsule proper, the dissection advancing on either aspect and around both poles of the kidney until the pelvis of the kidney is reached. Now and then the fatty capsule may be found so thickened and adherent, as the result of chronic perinephritis, that the scissors or knife may be required to separate it from the capsule proper. The kidney with its capsule proper is next lifted from its fatty capsule bed, and, if possible, delivered through the wound. The capsule proper is divided on a director along the entire length of the convex external border of the kidney and clean around the extremity of either pole. Each half of the capsule proper is in turn stripped from the kidney and reflected toward the pelvis until the entire surface of the kidney lies raw and denuded before the operator. In separating the capsule proper from the kidney, care must be exercised not to break or tear away parts of the kidney, which is often both very friable and very firmly connected with its capsule proper. The stripped-off capsule proper is next cut away entirely, close to its junction with the pelvis of the kidney, and removed. Delivery of the kidney makes this otherwise difficult work easy. If the kidney cannot be delivered, the capsule proper must be entirely peeled off the kidney by the fingers in the bottom of the wound, and excised as far as possible, any remaining portion being simply reflected backward around the root of the kidney, where it will curl up and stay. The kidney is dropped back into its fatty bed and the external incision is closed. Drainage, except when the parts are extremely œdematous, is dispensed with. After both kidneys have been thus operated upon, the dressings are applied and the patient is put to bed.

The safe performance of decapsulation of both kid-

neys at one sitting presupposes familiarity with kidney-work on the part of the surgeon. A surgeon unfamiliar with kidney operations, and consequently either too slow or too hesitant and timid, is not the right man in the right place in operating for chronic Bright's disease.

Excision of the renal capsule proper accurately defines the operation. It is, however, a long name, and either renal decapsulation, renal decortication, renal denudation, nephrocapsectomy or nephrocapsasectomy (*νεφρος*, a kidney; *καψακιον*, a capsule; *εκτομη*, a cutting out, or excision), may, should the operation survive, come to be preferred.

Ether was the anæsthetic employed in all of my operations but one, on these eighteen sufferers from chronic Bright's disease. Upon many of them I performed operations additional to the kidney operation, always under ether, and in not one instance was the slightest untoward effect observed. Case No. 18 was operated upon under combined nitrous oxide and oxygen anæsthesia conducted by Dr. Thomas L. Bennett. I see no good reasons why any surgeon should not use, in his operations upon the kidney, the same anæsthetic to which he is accustomed in his operative work generally. Personally, I would prefer, especially in cases of far advanced Bright's disease, nitrous oxide and oxygen, provided I could always command the services of an expert like Dr. Bennett to administer the combined gases; otherwise I would choose ether. My third choice would be spinal cocaine anæsthesia, which I have found particularly well adapted for work upon the kidneys.

There has thus far been no mortality in my operations upon the kidneys of patients affected with chronic Bright's disease. All of my patients recovered from the operation and, as far as my knowledge goes, all but two are alive to-day. One of the two died after an operation for ruptured tubal pregnancy, performed by another surgeon, exactly one year after my operation on her kidneys; the other succumbed to a hysterectomy, also performed by another surgeon, eight years after my operation on her right kidney.

That this favorable showing as regards the mortality will continue can scarcely be expected, when we consider the widespread changes in the system produced by chronic Bright's disease, and the operative risk which the patient, in view of the hopeless nature of his illness, is justified in assuming. My patient, No. 17, came to the operating table in a state of impending dissolution, with the full understanding on the part of herself, her family, her physicians, and myself, that she might die on the table. She was literally snatched from the jaws of death by the operation.

A combination of fortuitous circumstances, largely a matter of mere luck, prevented almost certain death during or after operation in several patients having the operation under consideration.

A colleague of high standing, a professor at one of our medical schools and attending physician to a large general hospital, was consulted during the past summer by a patient of thirteen, suffering from chronic Bright's disease dating, to the doctor's personal knowledge, from an attack of scarlet fever at the age of five, and existing continuously since that time. At the time of consultation the patient was in much better condition than usual. The doctor, who was familiar with my work, advised him to place himself under my care for operation on both kidneys; but in view of his good general condition, the hot weather, and the fact that the doctor was about to leave town for a month's vacation, thought that an additional four weeks, in a disease which had already lasted eight years, would make no material difference. The operation was, therefore, set down for a date within a few days after the doctor's return. Two and a half weeks following the consultation, the doctor received word from his substitute in town that the boy had died in uræmic coma and convulsions. The comment made by the doctor was that we can never tell when a patient with chronic Bright's disease will die. A second patient, with chronic Bright's disease and extensive secondary vascular changes, died suddenly of heart failure four days after operation was first proposed to him, and while deliberating the proposition. A third patient, an otherwise promising case in a man of thirty, had just been purged and sweated out of the uræmic state by his physicians, and was quite ready for operation, when a new feature in his case, a pericardial effusion, put in an appearance. Beyond all reasonable doubt, operation would not have prevented the death of the first two of these patients, and would have caused the death of the third.

The results of my operations for chronic Bright's disease, as far as a diligent and persistent search has enabled me to obtain them in each case, are presented in Table I. Before drawing deductions from an analysis of this table, it will be necessary, in the first place, to throw out three cases (Nos. 2, 9, and 10) which disappeared from observation in from four to six weeks after operation, and whose further and present whereabouts cannot be ascertained.

Among the nine patients operated upon a year or longer ago, Case No. 3 represents the only failure radically to cure the chronic Bright's disease existing at the time of operation. Operation was performed upon the right kidney in May, 1893. The kidney was found extensively diseased, its surfaces being nodular, and the capsule proper irregularly thickened and very adherent, as a result of inflammatory changes. The kidney contained a cyst, four centimeters in diameter, the contents of which, a turbid serum, were evacuated by incision through the kidney substance. The wound of the kidney was closed by a running catgut suture, and the kidney was anchored in the usual way. Some three years after my operation on the right kidney, another surgeon removed the left kidney. For five years thereafter the patient lived with only the right kidney, and at the end of that time this kidney, although, according to her physician's statement, still the seat of inflammation, was apparently in sufficiently good condition to warrant hysterectomy at the hands of a third surgeon, ten days after which last operation she died. It is difficult to understand how she managed to live for eight years after my original operation, five of them with only the kidney operated upon by me, unless that kidney had considerably improved over the condition above described as found at operation.

Four of my cases (Nos. 13 to 16, inclusively) were operated upon but a little over six months ago. In two of them the urine is at present free from albumin and casts; it is yet, however, too early to speak of a permanent cure. One of the remaining two shows great improvement, and in the urine of the other, according to Professor Brooks, there is at present only very slight evidence of renal disturbance. These four cases are encouraging, but the period of observation after operation is considered too brief to speak either of permanent cure or permanent improvement.

The time elapsed since operation in my last two cases (Nos. 17 and 18) is as yet too short to warrant deductions of any great or very legitimate value. They present features of such an interesting character, however, that I cannot refrain from giving them somewhat in detail.

Case No. 17.—Mrs. M. S., aged thirty-three,

mother of one child. Dr. T. W. Vardon of Galt, Ontario, Canada, her family physician, to whose kindness I am greatly indebted for the history of the patient prior and subsequent to operation, states that albumin was first found in the urine in 1896. During and since her only pregnancy, which terminated on May 5, 1899, with the birth of a child at term, she has suffered continuously from chronic Bright's disease, which ran its usual downward course, in spite of all the care in the way of nursing and treatment which the patient's fortunate situation in life enabled her to command. On about September 20, 1901, she was seen by Dr. H. Howitt of Guelph, Ontario, Canada, in consultation with Dr. Vardon. Dr. Howitt, whose acquaintance it was my good fortune to make on the occasion of a recent visit to Canada, and to whom I had detailed somewhat my experience in the operative treatment of chronic Bright's disease, had the courage to assume the responsibility of recommending operation at my hands. In a letter from Dr. Vardon, dated September 23, 1901, the patient's condition, at that time, is described substantially as follows: "The patient passes twenty-seven ounces of urine per day; specific gravity, 1,020; contains 50 to 70 per cent. of albumin and abundant casts. Dropsy of lower extremities; small accumulation of fluid in abdomen. Pulse, 100; temperature, 99° to 101° F. Sits up two to three hours per day, and can walk a little. Swelling of face at times, but no headache for several weeks past." There was some delay in acting upon Dr. Howitt's advice, during which the patient sank rapidly in spite of high pressure treatment. The quantity of urine steadily diminished, until, for about two weeks preceding operation, only ten to twelve ounces were passed in the twenty-four hours. On October 12, the distended skin of both lower extremities was incised at several places to permit of the escape of the dropsical effusion, and on October 15 two and a half gallons of fluid were withdrawn from the abdomen by the aspirator. These measures were advised by Dr. Howitt, and carried out by Dr. Vardon, with a view to preparing the patient for operation.

I saw the patient for the first time on the day of operation, October 17, 1901. Her face presented the characteristic pallor and puffiness of advanced Bright's disease; she was completely water-logged, and unable to breathe in the recumbent posture, being compelled to sit bolt upright in bed, day and night. Pulse 120, soft and compressible; temperature, a trifle above 100°; respirations, 30 per minute; œdema of the entire lower lobes of both lungs. It was very evident that her end was fast approaching. With some misgivings as to the chances of the patient surviving it, operation was undertaken at the Galt General Hospital, with the kind and efficient assistance of Drs. Howitt and Vardon, Dr. J. S. Wardlaw skilfully administering ether. The bleeding was minimal, but water poured from all the tissues cut, and operative procedures were difficult on account of the depth of the wound caused by the œdematous condition of all the parts overlying the kidneys. Excision of the capsule proper of both kidneys, after the method already described, was performed as expeditiously as possible. Both kidneys were considerably enlarged and succulent, and presented all the characteristics of far-advanced, chronic parenchymatous nephritis, forming typical examples of the so-called large, white kidney. The patient was returned to her room forty-five minutes after leaving it; that length of time sufficing for inducing anæsthesia, cleansing the operative field, completing operation upon both kidneys, and applying the dressings. A few strands of silkworm gut were placed, chiefly to drain off serum, and the wounds were closed for primary union. The strands were withdrawn by Dr. Vardon a few days later, and both incisions healed by first intention.

For a few days after operation her condition continued critical, or rather grew more so, a temperature of 103.8° F., with a pulse of 132, and respirations numbering 42 to the minute being reached on the fifth day. After that there was slow but continuous improvement in every symptom. The daily amount of urine for ten days following operation varied between two and fifteen ounces, with a total of ninety-two ounces, and two lost voidings, for the ten days. From the eleventh day on, the daily quantity of urine steadily increased, until it reached forty-four ounces on the 20th, and high-water mark, fifty-five ounces, on the thirty-sixth day after operation. The facts with regard to the urine are of special interest, as sustaining my conception of the way in which my operation acts in bringing about this good result, a subject which will be again referred to later on.

At date of the last report received from Dr. Vardon, December 1, 1901, the general dropsy and the pulmonary œdema had gradually and entirely disappeared. There was, however, a slight tendency to reaccumulation of fluid in the abdomen, a fact which suggests the possibility of a cirrhosis of the liver complicating the chronic Bright's disease.

"Mrs. S. is able to rest and sleep in the horizontal position, without even a pillow, and without the least distress. She is gaining in strength, has no pain in the head or other parts of the body, feels, eats, and sleeps well, and is getting a better color. I hope to get her up this week."

The amount of albumin in the urine is at present 40 to 50 per cent., as against 50 to 70 per cent. prior to operation; casts of all kinds, large and small hyaline, coarsely granular, epithelial, and mixed, are present in great abundance. The quantity of urine voided during the thirty days of November amounted to 1,300 ounces, of which 390 were passed in the first ten days, 444 in the second ten days, and 466 in the last ten days of the month. The specific gravity has varied between 1,014 and 1,025, but the percentage of urea is still rather low. Unfortunately, an acute right pyelitis developed on December 5, the outcome of which, at the present writing, December 10, is still in doubt.

Case No. 18.—Mrs. C. B., thirty-nine years of age, mother of four children, suffered from nephritis and a fatty heart during her last pregnancy, which terminated, on February 12, 1901, with the birth of a living child at term. The first two weeks of the puerperium were uneventful, except for the persistence of nephritis. Then symptoms of mild sepsis developed, and an examination revealed a large tumor, sensitive to pressure, to the right of the uterus. During the subsequent progress of the case the sepsis increased, while the tumor-mass grew smaller and smaller with progressive involution of the uterus. On March 14, 1901, I first saw the patient at her home in Monsey, N. Y., in consultation with her physician, Dr. A. O. Bogert of Spring Valley, N. Y., to whom I am indebted for the above history, as well as for devoted and intelligent care and aid in the subsequent management of the case. Indeed, I am entirely within the bounds of truth when I state that the patient owes her life to the unremitting watchfulness and the skill and judgment displayed by both Dr. Bogert and her nurse, Miss Anna L. Merritt, in tiding her over the many desperate crises in the further progress of her illness.

On the occasion of my first visit the patient was profoundly septic, and examination showed a tumor, nine to ten centimeters in diameter, to the right of the uterus, and intimately connected by a broad

pedicle with the body of that organ just above its junction with the cervix. The flabby uterus, measuring twelve to thirteen centimeters in depth, was crowded to the left and backward by the tumor; its interior was clean, and the lochia were sweet.

A diagnosis was made of uterine fibroma undergoing necrosis or gangrene, and inducing general sepsis; and removal of the tumor was advised as affording the only possibility of saving her life. The advice was accepted, and the operation was performed under ether anæsthesia at the patient's home, on March 17, 1901. The uterus, containing the sloughing fibroid above mentioned, together with a number of younger fibromata, was removed in one piece with both tubes and ovaries by abdominal section. The abdominal incision was closed, and free drainage established in the direction of and through the vagina.

The patient was returned to bed in a state of profound collapse, from which she was only just beginning to rally, when, on the day following operation, a double pneumonia of the most severe type developed. The pneumonia ran a stormy course of ten days, during which the temperature reached 104° F., the pulse 170, and the respirations 67 to the minute. During all this time her life hung on a thread, and the heart was kept going only by stimulation to the limit, no less than 86 hypodermics of caffeine, glonoin, camphor, and other cardiac excitants being administered within a week. The fact that for two weeks the fæces and urine were passed involuntarily and unconsciously will convey some idea of the low state of the patient.

During convalescence from the pneumonia a urinary fistula developed, which a cystoscopic examination showed to be due to a small slough of the bladder wall just above the orifice of the right ureter. The abdominal wound, which had healed by primary union, also broke down as the result of a pneumococcus infection.

For two weeks after resolution of the pneumonia the patient did fairly well, though her condition was not entirely satisfying. An attack of acute infection of the right kidney then developed, characterized by a painful swelling of the right kidney, with pyuria and a decided increase in the amount of albumin and the number of casts habitually present in the urine, followed by symptoms of secondary general sepsis with a temperature of 104° F. and a pulse rate of 120. On April 24, Professor A. Caillé saw the patient in consultation with Dr. Bogert and myself. We all agreed that infection of the right kidney was at the bottom of her present troubles, and Professor Caillé was inclined to regard it as a late pneumococcus infection. Removal of the right kidney was discussed at the time, but the patient's low condition, and the rapid abatement of the acute symptoms on the following day, led us to defer operation. During the months of May, June, and July, the patient had three exactly similar outbreaks of severe manifestations of infection of the right kidney, each attack lasting from eight to ten days. In the intervals between the attacks there was remission, but never complete disappearance, of the septic symptoms. During the July attack, the temperature ran up to 105.5° F., with a pulse rate of 160, and the patient was prostrated to the verge of death. It was resolved to hazard a right nephrectomy as giving her the only chance, and a slim one at that, for life. The operation was performed under ether, at the patient's home, on July 9, 1901. The large right kidney, riddled with innumerable abscesses, and with its pelvis filled with pus, was removed, and the wound dressed in twenty minutes, the necessity for haste being especially urgent. The patient bore the operation and rallied unexpectedly well.

Professor H. T. Brooks reported as follows upon the specimen: "Microscopic examination of sections made from kidney of Mrs. B. showed typical histological characteristics of multiple abscess. In the abscess areas there was found a thick bacillus, corresponding morphologically to a species of proteus, a class frequently responsible for suppurative nephritis."

Following the operation of removal of the septic right kidney there was a marvelous and rapid improvement in the patient's condition. The abdominal incision and the vesical fistula, which for over four months had refused to heal, closed spontaneously within ten days after operation. The lumbar operation wound which, on account of accidental contamination with pus from the kidney, had to be drained, was brought together a few days later for secondary union, and was firmly healed in less than three weeks after operation, at which time the patient left her bed. Appetite and strength rapidly returned; she gained thirteen pounds in weight, and gradually resumed her usual occupations, even coming to the city several times on visits. There was only one drawback to her happiness, and one source of uneasiness to her family and physicians—the persistence of albumin and casts, with small quantities of pus, in the urine. Professor Brooks called it chronic Bright's disease, with some insidious infection of the kidney.

As time wore on, the improvement in health ceased and the characteristic pallor, puffiness of the face, and œdema of the lower extremities, due to chronic Bright's disease, came to the foreground. Her husband, who knew of my operations upon cases of chronic Bright's disease, asked that his wife be given any chance afforded by operation, and the patient concurred in the request.

On November 10, 1901, I performed excision of the capsule proper of the left kidney, at the home of the patient. Nitrous oxide and oxygen anæsthesia was skilfully induced and maintained throughout the operation by Dr. Bennett, who at both previous operations had administered the ether. The operation was completed in thirty-two minutes; the patient regaining full consciousness immediately thereafter. The wound healed by primary union throughout. The kidney acted well, the daily amount of urine passed during the first twelve days averaging no less than seventy-six ounces, with an average specific gravity of 1,010, rather remarkable work for one kidney.

A minute piece of kidney tissue, which came away with the capsule proper, was sent for examination to Professor Brooks, who reports as follows: "Microscopic examination of the small piece of renal tissue removed from the kidney of Mrs. C. B. showed decided histologic evidence of multiple foci of nephritis of infectious (septic) type. As far as was possible to determine from the minute size of the cortical tissue received, these foci were confined to the areas corresponding to terminal arteries, and consequently had a wedge-shaped outline. In the diseased areas the tubules presented granular and partially disintegrated epithelia, often detached from the membrana propria, and the lumina were not infrequently occluded by polynuclear leucocytes (pus), fragmented epithelia, blood cells, and amorphous detritus. Some tubules were filled with dense hyaline material (casts)."

It will be seen from the above that the prognosis as regards the ultimate result in this case is unfavorable, owing to the presence of pus in the kidney. Thus far the infection has been more or less con-

trolled by urotropin, which has been steadily administered for many months past. At the present writing, December 10, the patient is again out of doors, and is feeling perfectly well.

Leaving out of consideration, for reasons already sufficiently detailed, these ten cases, we have left eight patients, observed from one year to over eight years after operation, the further progress of whose cases and whose final condition fully justify the title of this paper. These eight patients were all cured of their former chronic Bright's disease, and seven of them (Case 11 having meanwhile died an accidental death) remain so cured, as a result of operation on their kidney or kidneys, none of them having received further treatment of any kind after operation. They are free from all symptoms referable to the kidneys, and their urine remains permanently free of albumin and casts. My authority for the latter statement is Professor H. T. Brooks, who has made repeated examinations of the urine after operation in every case except one (Case No. 11), his examinations in six cases extending over a number of years.

Table II presents at a glance the duration of chronic Bright's disease prior to operation, as far as known, in each case; the time elapsed between operation and the final and permanent disappearance of albumin and casts from the urine, and the period after operation at which the continued health of the kidneys was last verified by examination of the urine.

TABLE II.

AUTHOR'S CASES OF CHRONIC BRIGHT'S DISEASE CURED BY OPERATION

CASE NUMBER.	1	4	5	6	7	8	11	12	
Known existence of chronic Bright's disease prior to operation, expressed in months	12	7	—	3	2	2	3	—	
Time from operation to final and permanent disappearance of albumin and casts from urine, in months	1	12	1	5	4	3	—	—	Average for seven cases, 4½ months.
Period of observation from operation to last examination of urine, in months	21	—	66	45	34	1	12	12	Average for eight cases, 24½ months.

That chronic Bright's disease is curable by operation is demonstrated, I believe, beyond any legitimate doubt by the results obtained in these eight cases. The significance of this demonstration or proof becomes apparent when we consider both the wide prevalence of the disease and its inevitable tendency to a fatal termination, delayed though that termination may be, under any and all forms of treatment hitherto known.

Let it not be understood, however, that I entertain any enthusiastic hopes or expectations that chronic Bright's disease will be found to yield to surgical treatment in all cases and in all stages of the disease. When the patient is practically moribund, sufficient time may not be left for the circulatory changes in the kidneys, initiated by the operation, to produce any good results. I have already pointed out that the first beneficial effects of operation, as indicated by the increased flow of urine, do not appear before the tenth day. The manifold complications of the advanced stages of chronic Bright's disease, many of them in themselves necessarily fatal, will also stand in the way of our saving lives, even if we succeed in curing or improving the chronic Bright's disease. A number of these complications will, in addition, prove almost prohibitive to undertaking any operation whatsoever. The improvement noted after operation in some of the extremest and most desperate cases, for example, Nos. 14, 17, 18, is certainly most encouraging, and a final good result in any of these three cases will go far toward solving the problem of the limitations of my operation.

How does operation act in bringing about a cure or improvement of chronic Bright's disease? The answer to this question has, to my mind, been settled as a result of observations made during the course of three operations upon kidneys that had previously been operated upon, one by myself and two by other surgeons. In each instance, nephropexy was the operation originally performed. At the second operation upon the same kidney the following conditions were noted as results of the first operation: First, the formation of strong connective-tissue adhesions or bands attaching the kidney to its surroundings. Secondly, the existence, in these connective-tissue adhesions or bands, of very large and numerous blood vessels running between the kidney and the adjacent tissues. This fact was forcibly brought home to my assistants and myself by the necessity of ligating artery after artery of considerable size, in dividing these adhesions. Thirdly, the predominance in number and size of the newly formed arteries over the newly formed veins. Fourthly, the significant fact that in all the arteries the direction of the blood stream was *toward* the kidney.

The conclusion which I had reached, that arterial hyperæmization of the kidney was the basic factor underlying the subsequent changes which resulted in a cure or improvement of chronic Bright's disease after operation, was clinched when I casually happened across the following passage in E. Ziegler's "Text Book of Special Pathological Anatomy." The Macmillan Company, 1897, page 909. Ziegler writes: "When a portion of the renal epithelium has been destroyed by a morbid process which spares the interstitial struetures, the loss is in general soon made good by regenerative proliferation of the remainder; and if the circulation is adequately maintained the new epithelium presently becomes capable of carrying on the secretary function."

The increased and adequately maintained blood supply to the kidney established by my operation leads, most probably, to gradual absorption of the interstitial or intertubular inflammatory products and exudates, thus freeing the tubules and glomeruli from external compression, constriction, and distortion, and permitting the re-establishment in them of a normal circulation. The result of this improved circulation in and between the tubules and glomeruli is the regenerative production of new epithelium capable of carrying on the secretory function.

That the cure of chronic Bright's disease is only initiated by operation, and is thereafter only gradual and progressive, is self-evident from the above considerations. The very fact that the final and permanent disappearance of albumin and casts from the urine required from one to as long as twelve months after operation indicates this, and at the same time furnishes proof, if such be needed, of the correctness of my explanation of the manner in which operation acts in bringing about a cure of chronic Bright's disease. It is not a question of the simple relief of renal tension, the beneficial effects of which in acute conditions of the kidney, described by Harrison in 1896, have since been noted by an increasing number of surgeons. In these acute cases the tight fit of the capsule proper is manifest, and the kidney bulges at once through an incision or puncture made through the capsule. In chronic Bright's disease, on the contrary, the capsule proper, although it may be abnormally adherent to the kidney, never compresses the latter, and may even sit loosely upon it. Moreover, on cutting the capsule proper, the edges of the incision do not gap. It is interesting to note

that Harrison, in his very recent communication, thinks that puncture to relieve renal tension in acute cases of nephritis may prevent them from advancing to the chronic stage.

Excision of the renal capsule proper, or renal decapsulation, is not in itself a new operation. It has been employed by Rose, quoted by Wolff, Ferguson, and occasionally by the writer, as part of the technics of nephropexy. The proposition, however, to treat chronic Bright's disease by bilateral renal decapsulation as a basic operation is original with the writer.

As already stated, my first five operations upon kidneys the seat of chronic Bright's disease were simply nephropexies, performed with the object of getting rid of severe symptoms due to mobility of the kidney or kidneys. The observation that the chronic Bright's disease in three of them was cured as a result of the operation led to the further evolution of the subject as presented in this paper. One practically identical observation is recorded by Wolff as following a nephropexy performed by Rose. At the operation, the kidney was found to be the seat of well-marked chronic nephritis, while examination of the urine made several years later showed both kidneys to be healthy. No practical deduction, however, was drawn by either Wolff or Rose from this observation. Somewhat similar observations are recorded by Newman and Ferguson. Newman performed nephropexy in two cases of movable kidney with intermittent hydronephrosis, in which casts appeared in the urine during the attacks, and found that the casts disappeared permanently after operation. Ferguson operated upon two kidneys, in the first of which "no diagnosis was made, but a stone in the kidney was suspected and exploration advised," while in the second, operation was undertaken upon the diagnosis of "septic kidney." On operation, both proved to be uncomplicated cases of acute or subacute nephritis. Nephropexy was performed upon both patients, and was followed by the prompt disappearance of albumin and casts from the urine.

Ferguson's two patients were operated upon early in 1899. As a result of the outcome in both, though after a period of observation extending over a few months only, Ferguson, in June, 1899, seconded my proposition, made in April, 1899, to treat chronic Bright's disease surgically. Neither Ferguson's paper nor my own, however, has received much attention, and no other publications of the same tenor have come to my knowledge.

In each of the cases cited from Harrison, Wolff, Newman, and Ferguson, one kidney only was operated upon, while in the large majority of my own cases, operation was performed on both kidneys. Harrison, indeed, believes that operation on one kidney may relieve the other. His observations, however, on which this opinion is based do not include cases of chronic Bright's disease.

We have seen that renal decapsulation is performed with the object in view of creating new and liberal supplies of arterial blood to the diseased kidney. How does the operation effect this object, and can the same object be effected in a better way? In answer to this question, it is simply necessary to point out that both the denuded kidney and its fatty capsule are most liberally supplied with blood vessels; that both are brought together by my operation over the whole extent of the surface of the kidney; and that the necessary result must be the formation, on the most extensive scale possible, of new vascular connections between the kidney and the fatty capsule embracing it. The fibrous capsule proper forms an almost impenetrable barrier to the passage of blood vessels between the kidney and its fatty capsule, as I have had abundant opportunity to verify in my operations upon the kidney. It is not at all uncommon, for instance, in operating upon a kidney, to find the blood vessels of the fatty capsule greatly increased both in number and size, generally as the result of a perinephritis. Now and then a large artery of the fatty capsule will be seen entering and apparently penetrating the capsule proper. On raising the capsule proper from the kidney, however, the artery is not severed, and further investigation shows that it does not enter the kidney, but is lost upon and in the capsule proper, which has thus intercepted a possible new blood supply to the kidney.

Practical clinical experience would seem to point to the same conclusions. In all the nephropexies upon patients suffering from Bright's disease, in which a cure or disappearance of the nephritis was noted as one result of the operation, in the case of Rose, reported by Wolff, in Ferguson's two cases, and in my own above listed, extensive or entire denudation or decapsulation of the kidney formed one of the features of the operation. Newman's two cases are not included, first, because they were cases of hydronephrosis, not of chronic Bright's disease, and secondly, because his technics are not specified in reporting the operations and their results.

Cirrhosis of the liver, chronic interstitial hepatitis one of the most frequent complications of chronic Bright's disease, has within the past three years come within the domain of surgery. The most modern development of the operation for cirrhosis of the liver embraces, as essential features, both the establishment of anastomosis between the omentum and the anterior abdominal wall, and the creation of widespread adhesions between the upper surface of the liver and the diaphragm. Both operations are performed with the object in view of relieving the portal circulation, and of thus removing one of the symptoms of the disease, the ascites. The writer believes that the future will show that whereas the anastomosis between the vessels of the omentum and abdominal wall will relieve the ascites, the establishment of broad adhesions and extensive vascular anastomosis between the upper surface of the liver and the diaphragm will accomplish more than this, It will probably lead to an amelioration, and possibly, in some instances, to a cure of the cirrhosis itself, by establishing an increased arterial hyperæmization of the liver on the same principles which underlie my operation for the cure of chronic Bright's disease. There is no good reason, at the present day, why a sufferer from both chronic Bright's disease and cirrhosis of the liver should not have the chance of life afforded by operation for both conditions. The day is not far distant, I believe, when we will read of operation upon both kidneys for chronic Bright's disease, and the operations above outlined for cirrhosis of the liver, as all performed at one sitting on the same patient. I see no reason, indeed, why they could not all be performed simultaneously through one and the same incision of the anterior abdominal wall.

Returning from this digression to the consideration of our subject proper, the cure of chronic Bright's disease by operation, I think we have shown, in the first place, that chronic Bright's disease is curable by operation, and, in the second place, that the present state of our knowledge does not warrant us in accurately defining the limits beyond which operation can no longer avail. As the result of my experience thus far, and from my present standpoint, I am prepared to operate upon any patient with chronic Bright's disease who has no incurable complication, or one

absolutely forbidding the administration of an anæsthetic, and whose probable expectation of life, without operation, is not less than a month. The latter proviso is made in view of the fact that the beneficial effects of the operation can scarcely become operative to any extent in less than about ten days.

The above conclusions are reached from my standpoint as a surgeon. From the patient's viewpoint the facts must be recognized that the treatment of chronic Bright's disease by operation forms an entirely new departure; that experience in this direction is limited to that detailed in this paper; that it will require time, and probably considerable time, before a larger and more definite experience becomes available; that no individual present sufferer from chronic Bright's disease can be certain of living to see an accumulation of such experience sufficient finally to settle the question, and that by delay he may imperil whatever chances he may at present have of being cured by operation.

In deciding for operation, it must be remembered that renal decapsulation is not directly and forthwith curative of chronic Bright's disease, but that it only leads to a cure or improvement of the disease by establishing circulatory conditions essential to such cure or improvement. The attainment of permanent cure, or of the full measure of improvement possible in a given case, will necessarily require time, during which the patient will, especially in the severer cases, stand in need of the further guidance and treatment of his family physician. The latter will come to regard the operation as one of the measures, albeit the most essential one, necessary to enable him to cope successfully with a case of chronic Bright's disease.

AN IMPROVED METHOD FOR INTRODUCTION OF THE STOMACH TUBE.

By H. CRENSHAW, M.D.
Atlanta, Ga.

Heretofore there has ever been the serious objection of nausea and much discomfort on the part of the patient to the use of the stomach tube. In the case of neurasthenic and hysterical individuals introduction of the tube is frequently impossible. If, however, the patient can be got to submit to a few introductions of the instrument, a tolerance is usually established, and the unpleasant accompaniments of this valuable diagnostic and therapeutic procedure disappear, at least to a considerable extent. But how to palliate these initiatory steps safely and effectively is the heretofore unsolved problem.

Cocainization of the fauces and pharynx has been resorted to by some, but is now pretty generally abandoned as dangerous and ineffective. The peculiar susceptibility of some persons to the drug, which must be applied in considerable amount in order to produce any result, has led most of those who have had large experience with the tube to give up the use of cocaine altogether.

But an effective and entirely safe method of preventing nausea occasioned by the stomach tube is that of freezing two or three inches of the extremity of the tube just prior to its introduction, the object being to secure slight temporary anæsthesia of the fauces and pharynx by means of the cold rubber. In this way cold is applied exactly where anæsthesia is needed, and the irritability is overcome. Thus the tube may be introduced for the first time with practically no gagging, straining, or nausea. The well-known anemetic procedure of swallowing ice offers a parallel illustration of the principle involved in the above method.

The extremity of the tube may be frozen by a few moments' spraying with ethyl chloride. The tube, of course, may be chilled in other ways, but the ethyl chloride is convenient and efficient. The tube has been found not to stiffen markedly under the influence of extreme cold, so no violence from the frozen rubber can occur. And by the time the tube reaches the cardia, its low temperature is sufficiently overcome to prevent any danger to the gastric mucosa, though the tube remain in the stomach some time.

It is not advised that the cold tube be used longer in any one case than is sufficient to accustom the patient to the use of the stomach tube, though there are stomachs so irritable that the introduction of the tube as ordinarily practised is never comfortable, when the cold tube is indicated for continued use.

The writer has made frequent successful tests of the principle herein set forth. Modifications, such as the use of an ice plug inserted in the end of the tube, have been tried, but the freezing of the extremity of the tube itself has proven most satisfactory.

RESULTS OF OSTEOTOMIES FOR THE CORRECTION OF GENU VARUM AND GENU VALGUM.

By HOMER GIBNEY, M.D.
New York.

Of the many hundreds of cases which present themselves at the outdoor department of the Hospital for Ruptured and Crippled, perhaps the most commonly met deformities of childhood are bow-legs and knock-knees.

These very naturally vary in degree from the slightest deviation from the normal to the most severe or corkscrew variety.

During the summer just passed, I have had the opportunity of operating on a number of these deformities at the Hospital for Ruptured and Crippled, and present a few cases showing the results, giving the age and condition at operation, tracing of deformity, and methods employed.

Cases of mild degree respond quickly to manipulation—always taught the mother—and properly built shoes. This method of treatment applies equally to bow-legs and knock-knees. In a number of cases where deformity is more marked, and where consent to operative interference is withheld, mechanical means are resorted to; and we employ the splints or braces used for many years at this hospital; (*a*) in bow-legs, where the bowing is confined to tibiæ, a long inner bar of steel extending from a point an inch above the condyle to a free joint at internal malleolus, to which is attached the foot-plate, the outer corresponding bar extending from tuberosity to external malleolus supporting outer portion of foot-plate. Inside of the outer bar and attached firmly to nearly the length of the inner bar is a cuff-shaped leather piece, divided in center, and perforated with eyelets which grasps two-thirds of the calf, and, when properly laced, makes uniform, steady pressure on deformity; and as this deformity decreases and the bones approximate more

nearly the inner bar, the old eyelets are cut away and new ones inserted, or, in many instances, new leather pieces are adjusted. The heel is held in the moulded leather cup by a cross-strap which is a triangular chamois piece, to which are attached bits of tape.

(*b*) Very nearly the opposite of this brace just described is employed in the correction of similar cases of knock-knee, except that for years we have made the outer bar extend from the trochanter, where a firm pad is held in place by a semi or, divided belt, to the bottom of the shoe, to which a heel a quarter of an inch thick is added. No joint at the knee or ankle, terminating in a right-angled circular stem pointing inward. This stem fits in a hole previously drilled in the heel, the leather cuff exerting constant pressure from within to outer bar over lower one-third femur knee-joint and upper one-third calf.

The more severe and those which come to operation, in many instances require protective apparatus only a short time, and not a few walk easily on the removal of plaster-of-Paris dressings. The method employed at the hospital, since operations were inaugurated, is the one I have done with very little if any modification—the *subcutaneous osteotomy*.

The legs are prepared as for any surgical operation. An assistant grasps firmly the thigh, the knee is held in semiflexion over a sandbag for supracondylar osteotomy, and on either side of the site of operation, for tibial osteotomy in bow-leg; the small osteotome is then forcibly pushed through skin and soft parts to the bone parallel with long axis; the osteotome, then at apex of greatest deformity, placed transversely, and with a mallet is driven into the ivory-like cortex of the bone. By gradually manipulating the osteotome, a line semicircular is cut down to the medullary canal, where less resistance is appreciable; withdraw gently the osteotome, and place a pad of gauze over the small opening made by the insertion of the instrument, the partial or incomplete fracture is in many cases easily effected.

This varies, however, according to the character of the bone, complete fracture being often done. The legs are then held carefully by an assistant or the operator; the wound, if oozing is marked, is sutured (single catgut sutures), dressed surgically, and put up in position of over-correction in plaster-of-Paris, in nearly all instances encircling and hugging the pelvis snugly.

CASE.	NAME AND AGE	DIAGNOSIS	CONDITION ON ADMISSION	OPERATION	RESULTS
	Female, 6 years.	Bow-Legs	General condition good. Marked outward bowing of legs, also marked anterior curvature of tibiæ, deformity mostly in lower quarter. (See Tracing.)	Osteotomy of tibiæ at point of greatest curvature. Normal fracture of fibula and tenotomy of tendo Achilles. Tissues stretched thoroughly to prevent overlapping of the end of bones. P. P. above knee, and limb put up in corrected position. Tenotomy also of right side.	Four weeks later P. P. removed, bony union firm. Bow-legs entirely disappeared and corrected. Tracing shows slight K. K. in former. (See Tracing.) Patient goes about without apparatus.
II	Female, 4½ years.	Bow-Legs Bilateral.	General condition fair. Patient shows evidences of former rickets. Deformity most marked below knees.	September 1[illegible]. Subcutaneous osteotomy of both tibiæ, and correction of deformity without complete fracture. P. P. applied, limbs in corrected position.	October [illegible]. P. P. removed to-day. Legs are absolutely straight. Bony union firm. There is some laxity of ligaments at knee-joint, this existed on admission. Patient going about without apparatus.
III	Male, 4 years	Bow-Legs	General condition fair. Marked evidences of rickets. Legs bowed in such position that feet are approximated. Knees about 1½ inches apart.	Subcutaneous Osteotomy of both tibiæ. P. P. applied in over-correction. Wound closed with one catgut suture.	P. P. removed. Deformity entirely corrected. No apparatus.
IV.	Male, 4 years.	Bow-Legs Double.	General condition fair. Evidences moderate Rickets. Bow-legs very marked, with greatest deformity at knees, at upper extremity of tibia.	September 2. Double osteotomy of tibiæ. Incision closed, catgut, limbs put in over-correction, and P. P. applied.	September 21. P. P. removed. Bony union firm. Deformity corrected and in good condition.
V.	Male, 4 years.	Bow-Legs Double.	Patient shows evidences of moderate rickets. Bow-legs very marked. Separation at knees 5½ inches; vertical 1½; greatest deformity above ankle. Child walks on outer border of feet. No spinal deformity.	August 27. Subcutaneous osteotomy lower third, both tibiæ. Limbs placed in position of over-correction and P. P. applied.	September 26. P. P. removed. There was some slight internal rotation and outward bowing in lower one-half tibia, also slight anterior curvature. These deformities over-corrected by secondary osteotomies and placed in P. P., which patient is still wearing. (See Patient.)
VI	Female, 4 years.	Bow-Legs.	General condition good, shows evidences of rickets. Bow-legs very marked, with greatest deformity below knee-joint.	August 2. Subcutaneous osteotomy both tibiæ. Incision closed with catgut suture, placed in over-correction, and P. P. spica applied.	August 20. P. P. removed. Deformity is corrected. P. P. reapplied until braces are ready. October 3, wearing braces and walks well.
VII	Male, 6½ years	Bow-Legs	General condition good, walks with marked limp. There was marked outward bowing of left lower extremity. Most marked in upper one-third leg. Marked lateral inclination to left side in standing. Has used braces and had osteotomy. Deformity is principally in left leg. Ra.—21¾. La.—17¾.	August 2[illegible]. Subcutaneous osteotomy 1½ to 2 inches above external condyle, higher than usual on account of great thickening. Radiograph shows bones much thicker than normal on each side knee-joint and ossification was irregular. Femur is ft. difficult to fracture. Decided curvature of tibia remained, and it was partially divided subcutaneously near lower third and deformity corrected without making complete fracture. Long P. P. spica applied, with deformity over-corrected.	September 28. P. P. S. removed. Bony union firm. Measured for leg support stiff at knee, free at ankle, and this to be attached to [illegible]-inch high shoe to overcome shortening.
VIII.	Female, 10 years.	Femoral Bow-Legs	Condition fair. Bowing of femurs, and besides deformity as shown by tracing there is marked anterior curvature of femur. Right limb is in flexion, and patella falls in space between condyles. Shaft of femur is rotated inward.	Supracondylar osteotomy from inside and limbs put up in double spica and in correct position, spica short just over pelvis.	September 10. P. P. S. removed. Union firm. Deformity corrected. To remain in bed few days. September 28. Patient up to-day, looks well. No apparatus.

No.	NAME AND AGE	DIAGNOSIS	CONDITION ON ADMISSION.	TREATMENT.	RESULTS
IX	Female, 4 years.	K. K.	General condition good; evidences of rickets, marked K. K. and anterior curvature of tibiæ	August 7, 1901. Double subcutaneous supracondylar osteotomy. Patient put in double P. P. spica, limbs in over-correction	August 22. P. P. S. removed; deformity corrected. Firm bony union at point of fracture. Two days later the anterior curvature was corrected by subcutaneous osteotomy of tibiæ and division of tendo Achilles. Deformity fully corrected. No apparatus. (See Patient.) Patient is R. & C. Hospital. Dressing now removed.
X	Male, 5 years.	K. K. (Double.) Congenital	Condition fair; evidences of rickets, anterior curvature of both tibiæ and slight rotary lateral curvature, with convexity to right. Marked flat feet	October 1. Supracondylar osteotomy, left femur; limb in corrected position in P. P. S. On right side, osteotomy of tibia and correction of anterior curvature. P. P. applied	(See Patient.) Patient is R. & C. Hospital. Dressing now removed.
XI	Male, 10 years.	Left K. K. and failure of development	K. K. very marked. Deformity in femur principally. Well-marked limitation of dorsal flexion at ankle due to original operations at ankle. Left femur 12½ to outer condyle, 2 inches shortening evidently in femur	August 1. Subcutaneous supracondylar osteotomy from outer side. Wound closed with catgut. Double P. P. S. applied, and limbs put upon bow-leg position	September 18. Deformity corrected; union firm. Dorsal flexion normal. Patient now walking inward. To have left shoe raised 2 inches. No apparatus
XII	Female, 4½ years.	K. K.	Child in fair condition, but undersize. There is marked rachitis, with deformity equally marked between tibiæ.	Double supracondylar osteotomy from outer side. Wounds closed with catgut. Double P. P. S. applied, and limbs put upon bow-leg position	Spica removed for cleanliness and reapplied on August 29, the spica again removed. Union firm. Deformity corrected, to have brace.
XIII	Male, 8 years.	K. K.	Marked rachitis on admission. On right side, well marked bow-leg. Deformity confined to tibiæ, which is twisted inward	August 12. Left supracondylar osteotomy and right osteotomy of tibiæ; limb in over-correction. P. P. S. applied	September 14. P. P. removed. Deformity corrected. Union firm. Right further corrected, and P. P. below knee and including foot.
XIV	Male, 4 years.	K. K.	General condition good. Marked K. K. Deformity being greatest in tibiæ. Did years of previous osteotomy. Knees hyperextended	August 13. Cuneiform osteotomy upper one-third both tibiæ; inner side. Deformity corrected. Periosteum and skin closed with catgut	P. P. removed. Marked recurvature still persists in part, due to backward bowing of tibia
XV	Female, 4 years.	K. K. (Double.)	Child undersize. Marked rachitis on right side. K. K. very marked on left side. K. K. slight	July 22. Double, subcutaneous supracondylar osteotomy. Bones split, fracture not complete. P. P. S. (Gibney) applied, limbs in position over-correction.	August 21. P. P. removed; deformity corrected. Union firm. There is slight outward bowing of tibia. Measured for K. K. braces, now being worn.
XVI	Male, 4½ years.	K. K. (Double.)	Evidences, marked rickets. Extreme K. K. and deformity of tibiæ. Marked anterior curvature of tibiæ	August 6. Double subcutaneous osteotomy. Limbs placed in bow-leg position; deformity corrected. Double P. P. S. applied. October 1. Osteotomy of both tibiæ and anterior curvature corrected. P. P. applied as usual.	Solid union. Deformity corrected. Child now in hospital for operation on October 1.
XVII	Female, 5 years.	K. K. (Double.)	General condition good. Marked K. K., both sides	Double supracondylar osteotomy, legs put in corrected position. P. P. S. applied.	Now in R. & C.
XVIII	Female, 6 years.	K. K.	General condition good. In addition to the deformity, as in tracing, there was genu recurvatum and anterior bowing of femur. Both trochanters are above Nealta line. Bones bend under pressure. Child also has rotary lateral curvature and bilateral rachitic varus. Normal teeth. Shape of head characteristic. Marked laxity of ligaments.	Supracondylar osteotomy on left side and cuneiform section of tibia on right side. Incision closed with catgut suture, dressed in usual way. Double P. P. S. applied, with limbs in bow-leg position.	P. P. removed. Bony union firm. Still marked laxity in ligaments in knee-joint. P. P. applied again, to be worn until braces are ready for fitting.
XIX	Male, 4 years.	Bow-Legs and anterior curvature of tibia.	General condition fair, shows evidences of marked rickets, standing in rachitic attitude, hips rotated inward. La. = 1½. Ra. = 1½.	Osteotomy of both tibiæ; limbs placed in corrected position, and P. P. applied. Limbs were over-corrected and later P. P. was removed and reapplied in slight over-correction	Union firm. Deformity corrected. Child walking about in good condition. Ra. = 14½. La. = 14½. Total increase, ½ inch.
XX	Male, 4 years.	Bow Legs.	General good condition, stands in typical bow-leg attitude. Deformity most marked at knee, and is equally divided between lower end of femur and upper end of tibia	Double subcutaneous osteotomy of tibia and deformity corrected without complete fracture. P. P. applied in over-correction.	Deformity of tibia is fully corrected. There is a slight outward curve of femur, with malleoli approximated, condyles separated, ½ inch. Patient measured for bow-leg braces.
XXI	Female, 15 years.	Deformity after excision at knee joint	Patient was operated on when about ten years old; improved, but about two years ago limb began to contract at site of former excision, knee flexed at 90°, a. g. e. 90°, a. q. f. 90°; Rth = 13½, Lth = 23; Rk = 14, Lk = 14½; Rc = 11 — Lc = 11½; Ra = 11½ (?); La. = 12 inches. There is subluxation and ankylosis at knee. No patella	May 25. Supracondylar osteotomy and leg straightened to 126° P. P. applied. July 5, P. P. removed, good union, leg stretched again to 143°. August 20, again stretched, a longitudinal incision made over tubercle of tibia, also incision of periosteum, cuneiform osteology and leg almost in complete extension. K. K. deformity corrected. P. P. to thigh and including foot	October 7. General condition excellent. Limb in good shape and wounds all closed. A. G. E. 166°. Patient walks well and will wear long spring brace.

At the expiration of two weeks or perhaps three, depending on cleanliness and habits of child, the dressing is cut down, position of limbs observed, and still further over-corrected, as in some instances it is necessary, and the legs again put up in plaster-of-Paris, lighter this time, and measurements taken for apparatus. This is worn after the discontinuation of plaster-of-Paris, to prevent relapse. Cases of moderate degree, and those which are active and allowed up and about the ward, soon after operation, do remarkably well, if made to wear protective or corrective apparatus at night.

A METHOD OF PROTECTING THE PERINEUM DURING LABOR.

By L. E. NORFLEET, M.D.,
TARBORO, N. C.

PROMPTED by the satisfaction derived from the practice of this method, I have, much against my usual inclinations in such matters, decided to offer it as something new in the field of this much-written-about subject. Some ten years since, while acting as house physician to the Sloane Hospital, I became so dissatisfied with all the textbook methods of helping the perineum through the ordeal of labor that I made a very close study of my cases of rupture, both as to cause and prevention, with the result that where in the beginning I had almost begun to think that a certain percentage of labor cases would tear in spite of all treatment, in the end I reached the conclusion that such a result could almost always be prevented. Since using my method, I have positively not seen a tear that even the most enthusiastic surgeon could think necessary to suture, nor have my patients found it necessary to seek the aid of a gynecologist to suture the body later on. I know this is a pretty strong statement, but I am willing to stand by it. I will, however, state that I have never seen a persistent occipito-posterior presentation, but I have used my method successfully in several face cases. In breech cases the method is of no use.

Before I present my method, I would like to say a few words as to what I consider the cause of rupture in the vast majority of cases. I do not think I ever saw a single rupture due to the fact that the head was too large to pass through the vulva under any circumstances, though I suppose such a disproportion may occur with monstrosities, or in cases of maternal pelvic contraction; but in the latter class of cases the contraction would probably prevent the head ever reaching, much less tearing, the perineum.

On the other hand, I have seen many a tear occur and when I examined the child's cranial development, I was mortified to find all its measurements moderate, while the mother's vagina was seemingly perfectly normal in size. In these last cases, however, the labor was characterized by the so-called "stormy pains," as a rule. These storm cases are really they key to my method, for from them I learned the cause of the rupture. These pains are nothing more than undue muscular contractions. No time is allowed for accommodation on the part of the fetal head, or stretching on the part of the maternal soft parts. The powerful abdominal muscles force the head down, with the help of the uterine contractions. At the same time the auxiliaries, in the shape of the pelvic and perineal muscles, pull up the vagina and perineal body over it, until the perineum becomes as thin as paper and as tense as a "fiddle-string." Suppose we wished to produce a rupture of the parts, could we desire a more ideal condition? Now, another contraction comes on, and often I have seen the perineum melt away like wet blotting-paper, and the child's head born, without time being allowed for any extension at all. Rupture of the body may also occur in cases with very moderate pains, but here, also, as in the stormy cases, I believe the chief cause lies with the muscular action.

Granting my theory to be correct, it would seem that an ideal labor would be one without "pains;" but as I hardly expected to accomplish this happy combination, I had to look about for the nearest substitute. My forceps cases gave me my first hint. One invariable rule with those instruments was to give chloroform to full muscular relaxation, and then, with their help, bring the child's occiput well down under the pubic arch; then to extend the head only far enough to allow the fingers placed behind the mother's arms, to control it by pressure on the forehead. At this point the forceps was removed, and the labor completed by upward pressure on the child's forehead. In these cases muscular action was stopped, and instead of the perineum being tense, the chloroform relaxed it so that I have often seen one that a moment before looked impossible of salvation, now really wrinkle as the head passed out. It was a very rare occurrence for a tear to be found after our forceps; but here again I could hardly advocate the use of forceps in every labor case with the idea of saving perineum thereby; but, on the other hand, it seemed to me that it would be a good idea to let Nature bring the head down to the point where we had removed the forceps blades, and then at once stop muscular action with chloroform and complete the labor by manual extension. I tried this method, and both in hospital and private practice have been more than satisfied with the result, for not only does it help to save the perineum, but it also renders the woman unconscious of that climax of labor suffering—the passage of the head through the vulvar orifice; and this last point alone is enough to recommend its use.

Now as to the method itself. It is absolutely necessary to have some one, nurse, mother, or husband, who has some nerve, to act as assistant and take charge of the anæsthetic. Any one will do as the patient will only take enough to relax her, and then the chloroform can be stopped in a moment or two more. Explain to your assistant that when you give the word the woman must get enough chloroform to make her go to sleep, and show him or her how much of the drug to drop on the cone. Always see that your patient's bowels are empty, for your own comfort, as well as to prevent a loaded bowel keeping the head back. As the second stage comes on, give the patient a whiff or so of chloroform at each pain, both to ease her suffering and to get both patient and assistants accustomed to the use of the anæsthetic. Now, as the head comes down enough to separate the vulva, give the chloroform to your assistant, and with your fingers behind the woman's arms watch the child's head. Now, the occiput being well hooked under the pubic arch, a pain brings the extending head so far forward that the fingers feel the forehead slip under their control. At once give the word for full chloroform, and with the help of your left fingers on the child's occiput, hold the head still until relaxation takes place; then slowly shell the head out by pressure on the forehead. Take your time and do not go by jerks, but allow the perineum to stretch as much as possible. As soon as the head is out, throw your chloroform out of the room, and by the time you have seen to the child's eyes and mouth, the woman will be conscious, though she will not want to talk, but would rather sleep.

A very prominent New York physician once said to me that ruptured perinei, directly or indirectly, gave the gynecologists two-thirds of their patients. Having this in view, I offer my method for what it is worth, and ask for it only a fair trial from my fellow obstetricians, and I am sure they will save at least 95 per cent. of their cases from a tear.

Density of Population.—The density of population in foreign countries has, says the *Scientific American*, recently been computed. Great Britain takes the lead with 132 inhabitants per square kilometer, which is equal to 0.3861 square mile; then comes Japan, 114.4; Italy, 106.6; the German Empire 104.2; then comes Austria, 87; Hungary, 59.6; France, 72.2; Spain, 35.9; the United States, 8.4; Russia, 5.9.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, December 21, 1901.

RECIPROCITY OF LICENSURE.

THE great interest manifested by the profession in the relative standards of qualifications for the medical degree, and of the interstate reciprocity of different examining boards, has induced the MEDICAL RECORD to present to its readers a complete official account of the educational requirements of each State in reference to the points at issue. The British Provinces are for obvious reasons of comparison included in this list.

It is gratifying to note that in the majority of instances the laws governing the practice of medicine in the different commonwealths are reasonably stringent and well calculated to fulfill their aims. The exceptions to this rule are surprisingly few in number, and while the standard of fitness is necessarily variable as defined by different laws, it is nevertheless sufficiently high to hold wholesale quackery in effectual check.

In view of the strong feeling in favor of reciprocity of licensure, it may be a matter of surprise to learn of the number of States practically indorsing such a measure. Alabama, California, Delaware, the District of Columbia, Illinois, Louisiana, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Texas, and Wisconsin have fallen into line, and others are in a fair way to follow. The whole question hinges on equality of qualification, and the recognition of an absolute standard of fitness. In this regard there must be a proper agreement among the States themselves, as their independent sovereignty does not admit of a National law which might place each on a common level. Good progress is being made, however, toward a proper understanding with all parties concerned. The movement toward the required end must be largely evolutionary, following free discussion, and much missionary work.

Practically speaking, there is no question as to the desirability of universal reciprocity of licensure on the broad grounds on which it should be based. In some quarters there is a disposition to stickle for special forms, which are immaterial as affecting final results. The larger States have simple enough regulations to meet all requirements. Their laws are neither complicated, cumbersome, nor impracticable. The whole question of uniformity of requirements rests upon very simple propositions. Four years of study in a reputable medical college, a medical degree, and afterward an independent State examination for license is all that any one can ask. When such requirements are met in one State, they should not be exacted in another. There is a justice and equity in the matter that cannot be gainsaid. From a legal point of view, a man who has once proved his qualifications should be always qualified.

The mere fact that a physician who has practised for years in one State, and moving to another, is unable to pass a new licensing board, by no means proves that he is an ignoramus. He is often rusty on elementary subjects, and may thus be disqualified on a purely technical or arbitrary ruling. In this respect, what is mere child's play for the fresh graduate, is a veritable hardship to the older man. And yet this is what a new State examination means to many a capable practitioner. It is obviously unjust that he should be compelled to submit to them.

THE EVOLUTION OF SPECIALISM.

IN the good old times, the written and unwritten ethics of professional relations made it distinctly understood with all parties concerned that when once a patient put himself under the care of a physician, the latter necessarily owned him body and soul. It became, then, a matter of as much importance to the sick one to choose his medical adviser once and for all time as to embrace an article of faith in his religion. The family physician, when the stray sheep entered his fold became responsible for his safe-keeping until the time when the absolute and inevitable decree of nature made longer possession impossible.

Under ordinary circumstances, the advantages to both physician and patient were obvious enough in bringing them in constant and confidential relations with each other, and in enabling each to discharge those mutual obligations of trustfulness which should properly exist between them. Thus, the old family physician was as much the general adviser on all matters medical as was the priest or clergyman on matters spiritual.

It would be hard to prove, even in these days of advanced specialism, that the patient was much worse off then than now, if the actual statistics of general mortality are seriously taken into account. There was one element of safety in the treatment by the old-fashioned method, and that consisted in the practice of a forced and judicious conservatism, which was not so prone to interfere with nature's method of cure in the commoner diseases, and which thus offset some of the failures in the rarer ones. The family doctor became thus a good all-round man for ordinary emergencies. He could operate for hernia, tracheotomize a strangling infant, set a fracture, and perform version as effectively as he could blister a pleurisy, treat typhoid, venesect for pneumonia, or "physick" for dysentery. Hence he was the only one consulted when sickness visited his district.

Of course, some of his patients died for want of special skill, which he did not possess. On the other hand, no one was apt to suffer from overtreatment.

The possession of too much skill is in itself an element of danger. The deft operator is apt to use the knife too frequently. Any one who follows the discussion concerning the new operative procedures of the day need not be convinced of this fact. While some patients are saved, how many are lost as the result of absolutism in extremes? In the evolution of a new idea—a so-called improvement on nature—the scales are constantly shifting with the counter weights which are used. What physician or sur-

geon long in practice has not gone through countless epidemics of remedies and operative methods that have in the end made him immune against any undue enthusiasm? We have had notable exceptions to the rule, it is true; but the rule exists nevertheless. The mistakes in attempting to evolve the principle have equaled the triumphs of its establishment. The ovaries are not extirpated as of old, and even the appendix is sometimes left in its place to take its chances against the knife of the eager theorist. The everyday practitioner is oftentimes justly constrained, while reading the claims of rival disputants, to thank his stars that he can take the middle ground, and not be sorely tempted to be fashionably progressive and go beyond the range of his common sense. From this point of view, his function as general adviser to his clients is magnified rather than minified, and his hold on the confidence of his patient becomes correspondingly confirmed and safely impartial. If he makes himself worthy of such trust, he deserves to maintain his old-time function. His only interest, then, is to advise as to the best course, and to shift his responsibility only in such cases as circumstances may warrant. He thus becomes the true and rightful conservative element in deciding between inordinate zeal in one direction and absolute safety in another.

The claim is made by the general practitioner that specialism is robbing him of his business. This is certainly true to some extent, and is one of the inevitable results of the survival of the fittest. Taking into account the prevalent practices of patients to consult specialists at first hand and decide for themselves their needs in given cases, there are many chances of making wrong selections.

The ordinary expert is usually a man of one idea, a hobbyist by force of habit and by virtue of his education. He is not inclined to look beyond the special sphere of his work. As a gynecologist, his first thought is of the uterus as the pivotal point of his real interest in the patient. So with the throat man, the neurologist, the ophthalmologist, and the laparotomist. He need not look long in the direction of his favorite trend without finding something important to treat. Thus the part becomes greater than the whole, and so long as given and desirable symptoms exist, the patient is his, and the general practitioner looks on from the outside. When mere business is the consideration, the specialist is tempted to hold on so long as he can, and to force the refinements of his skill into unnecessary directions.

The question with the general practitioner is where such practices are likely to end. Obviously, the line must be drawn somewhere between the greed of the expert and the rights and privileges of the ordinary all-round man. In the treatment of general diseases, the family physician should have some voice in deciding upon cases actually requiring the skill of the specialist. He should certainly be better qualified to do so than the patient himself, and the recognition of relative rights in this respect would do much to combat the spirit of apparent antagonism between both classes of practitioners. If it is conceded that in cases requiring special operations the expert should have full temporary charge of the patient; it should likewise be granted that the general physician should not be blamed for treating the minor ailments of diseased organs when they present themselves in his ordinary line of work. There is ample room and abundant opportunity for both general practitioner and specialist, only the line has not yet been definitely drawn between the two.

CANCER AND SALT.

Dr. JAMES BRAITHWAITE has published in the *Lancet*, November 30, an article upon cancer, in which he puts forward the theory that there are four factors in the causation of the disease, excess of salt in food being the most prominent. Salt, he holds, is an essential factor, but requires one or probably two of the others to originate the malady.

The other factors are an overnourished condition of the system proceeding from the consumption of too much food, and especially of meat, and the impure condition of the body, resulting from the non-oxidation of the food. The fourth factor is local irritation or stimulation.

Dr. Braithwaite, who is on the staff of the Leeds General Infirmary, was struck by the almost complete immunity of the Jewesses, who attended the gynecological department of that institution, to cancer, there having been but one case in a period of ten years. Dr. Tunstall, late Medical Officer to Jewish Hospital for Incurables, gives corroborative evidence as to the rarity of cancer among Jews.

The argument is therefore made that this apparent immunity is either due to race or diet, the latter he claims as the more probable cause.

The Jews forswear bacon and ham; and as it has been shown that the pig is the only domestic animal never attacked by cancer, by the process of elimination, he concludes, it must be the salt and the flesh of the animal that are at fault. The Jews also eat less butcher's meat than do the followers of most other religions.

That diet has much to do with the incidence of cancer is a belief constantly gaining ground, and there can be no doubt that a large quantity of salt is consumed by civilized people; but the contention of Dr. Braithwaite, that where salt is absent, cancer is absent, appears quite untenable, if not absurd.

TICK-FEVER AND INOCULATION.

THE analogy between the disease of cattle variously known as "tick-fever," "red water," "Texas fever," and the malarial fevers of man is at the present time a source of much interest.

The Americans, Theobald Smith and Kilbourne, were the first to describe this disease, and to point out that it has for its essential cause, as in malaria, a microorganism, in fact, it has been greatly due to the investigations of these two men, that the connection between the mosquito and malaria and yellow fever was first suggested.

The English *Medical Review of Reviews*, November, calls attention to an article which appeared in the Australian *Medical Gazette*, giving an account of an important experimental inquiry into tick-fever, made by Dr. Frank Tidswell, Principal Assistant Medical Officer to the Government of New South Wales. Tick-fever occurs in Australia, Texas, Jamaica, the Argentine Republic, South Africa, Roumania, Java, Finland, Sardinia, Italy, Turkey, France,

Algeria, and Tunis. It is known to affect only horned cattle, and is not directly communicated from beast to beast, but under natural conditions is only acquired by an animal as a consequence of infestation by cattle ticks.

The important consequence of tick-infestation of cattle is tick-fever. It begins from 10 to 20 days after exposure, and lasts from 8 to 15 days, during which the temperature is between 103° and 107° F.

Dr. Tidswell defines the microorganism of tick-fever as an Apiosma (Pyrosoma) bigeminum. In the bovine host it is found in the red blood corpuscles, is usually in the form of a double (bigeminate) pear, or flame-shaped organism, sometimes as a more or less rounded body. The disease is really an acute infective anæmia, termed in Jamaica ixodic anæmia.

In America, it was first observed that native cattle had acquired immunity, and subsequent experiment showed that this is the case after undergoing an attack of tick-fever. Hence arose the practice of inoculating the blood of immune cattle, in the hope that the mild illness so produced would protect against the serious consequences of exposure to ticks.

Dr. Edington, Director of the Bacteriological Institute, Cape Colony, arrived at the following conclusions. (1) That the blood of animals, themselves healthy, from a red-water area is dangerous, if inoculated into an animal which suffers coincidentally from another disease. (2) That the blood of animals suffering from mild or modified red water may be safely used to inoculate a healthy animal subcutaneously, but is dangerous when injected into a vein. (3) That the subcutaneous inoculation of mild or modified red-water blood conveys a mild form of the disease, and since the blood of such an animal is virulent when injected into the vein of another animal, it is safely to be inferred that the animal suffering from the mild form becomes more or less immunized or "salted."

The result of the investigations of all observers, therefore, shows that inoculation confers a very considerable degree of protection upon healthy animals imported into a tick-district, and the deductions to be drawn therefrom may be of use when the question of malaria and yellow fever is considered from the standpoint of inoculation.

The Streets of New York.

Never within recent years have the streets of the city been in such a filthy condition as now. Building operations are in progress in every part of the metropolis of America, the subway construction has played havoc with many of the principal thoroughfares, the contractors of both buildings and subway evince a regrettable disinclination to remove debris or dirt caused by their work, nay, it would almost seem as if they took a pride in exhibiting their contempt for the public by littering the streets and sidewalks, in some instances, to an incredible extent.

Unfortunately, however, these are not all the inconveniences to which the inhabitants of New York are compelled to submit. For reasons, into which it is not within our province to delve, the street-cleaning commissioner seems to have practically suspended the work of his brigade during the past two or three weeks. The consequences have been an accumulation of filth in some of the streets which reminds one of the Cuban towns before they came under American administration.

The death rate of New York is greater than it should be, although whether this increased mortality is due to the laxness of the street-cleaning methods is not easy to prove. Probably so long as winter lasts the danger to health of unclean streets will not manifest itself conspicuously. But when the grasp of frost unloosens the microbes of disease lurking in the unsavory heaps of refuse, the mortality lists will be swelled accordingly.

The late Colonel Waring made New York a model of cleanliness, the policy of the gentleman who now holds the position of street commissioner would seem to be exactly to the contrary.

How to Increase the Library of the Academy.

The Committee on Library in their report to the New York State Medical Association make known to all save a comparative few of the profession the existence of a large collection of useful books which are hidden away in our midst as truly as though buried.

In lower Madison Avenue, once the neighborhood of the fashionables, in the old house left for purposes of science as a memorial to Dr. Valentine Mott, who died the closing year of our Civil War, are to be found upward of 10,000 bound volumes, besides catalogued and uncatalogued pamphlets. The shelves entirely filled, over 1,200 volumes are packed away for want of space.

This collection is made up of Dr. Mott's own valuable medical library, to which are added those of Dr. Bolton and Dr. Isaac Wood, with later additions from various sources.

One of the many functions of the Academy of Medicine in furthering the welfare of the profession is to afford ample library privileges. By degrees this institution has developed, by purchase and gift, a library of its kind, which, in size and medical value, is second to none in the United States.

It seems to us that it would be entirely legitimate for the Mott collection to be added to the library of the Academy. We would therefore advise the Academy to look into this matter, and take such steps as become necessary for the acquisition of the now buried treasures in the memorial building.

Cycling and Its Abuse.

The curse of cycling, as of course with many other modes of exercise, is the tendency to carry it to excess. A striking and pitiable example of this human failing has been recently given in Madison Square Garden, where, for a week, a number of men toiled round and round that hall for hours at a stretch, making a spectacle of themselves, and like the gladiators of old, providing the inhabitants of New York with a Roman holiday.

The brutalizing effect of contests of this nature was recognized two years ago, and laws were passed which seemed to minimize the severity of long-distance races.

Notwithstanding this legislation, the men who raced the past week appear to have suffered from the strain as much, if not more, as did the men who pedaled for the same period two years ago. Utterly exhausted, worn out in body and mind, several were forced to retire many hours before the stipulated time for the contest to end.

Those who stayed to the finish were kept going by stimulants and drugs, which imparted to them sufficient fictitious strength to endure through their appointed task.

Needless to say that such tests of endurance are useless, foolish, and even criminal. No good object is attained by bicycle riding of this description, and it tends to bring the exercise into disrepute. Some of the men who played tricks with their constitutions in

Madison Square Garden will suffer from the effects of their foolishness for years, perhaps for life. The heart is almost certain to be affected injuriously, and the strain put upon the nervous system is more than likely to sap the vitality of any but the strongest constitution. Medical journals everywhere should protest against bicycle riding—in itself a healthy exercise—being thus so grossly abused.

Conveyance of Wounded in Naval Actions.

The conveyance of the wounded in battles at sea between ships of the modern type is a problem that awaits a successful solution. Many attempts have been made to devise an apparatus which will meet the difficulties of the situation, but with no complete success.

Fleet-Surgeon Gilbert Kirker of the British navy read a paper at the last meeting of the British Medical Association in which he described a contrivance of his invention, and which he thinks is better than any now in use.

In the *Journal of the Association of Military Surgeons of the United States*, Dr. Kirker's paper is given with illustrations of his contrivance.

Dr. Kirker says that "an ambulance to be suitable for use on board ship must satisfy several conditions. It should be able to retain its occupant safely in all positions, from horizontal to perpendicular; it should be able to go into a hatchway by sliding down the ladder, or being lowered at any angle; it should be as short as possible in order to get easily round corners; and in confined spaces, where there is not room for two men to carry it, it should be transportable by one."

Dr. Kirker claims for his apparatus that it can be slung or suspended, carried as an ordinary stretcher, wheeled, barrow-fashion, on casters at the ends of the carrying handles which are hinged so as to fall back under either end of the cot to permit of its being trundled along the deck or passage ways, slid on its sleigh attachments down ladders or other inclines, or suspended from the head end perpendicularly; for lowering down narrow hatchways, etc., the occupant being secured in the cot by straps. Its weight is 35 pounds, its length 7 feet 2 inches when carried as a stretcher, and 6 feet 2 inches when the handles are folded back, its breadth is 21 inches at the head, 18 inches at the foot.

The contrivance of Fleet-Surgeon Kirker, which is a modification of M. Auffert's, in use in the French and Chilian navies, is undergoing official trial in the British navy.

Treatment and Management of Advanced Cases of Consumption.—Bernhard J. Zwar pleads for the open-air treatment, which, even if not curative, does certainly prolong the life of the patients, even of those apparently near death. The practice followed in his hospital is that with a maximum temperature of over 100° F., the patient is taken out into the open air in his bed, or is bedded on a lounge, while, with a temperature close on 100°, he is advised to rest on a lounge the greater part of the day. Patients able to get about are given carefully superintended, graduated exercise, which must stop short of fatigue. By the out-of-door treatment, cough is lessened, and nausea and vomiting rapidly improve and disappear. Morphine should be used as little as possible. Open-air patients usually sleep well, and have few digestive disturbances. A useful inhalation is one containing menthol and eucalyptol, of each 1 drachm, to 2 ounces of rectified spirit, and a teaspoonful of this added to a pint of water at 150° F. Carbolic acid, creosote, or other bases can be added to this as special occasions demand. *Intercolonial Medical Journal of Australasia.*

News of the Week.

Mortality Among the Troops in the Philippines.—A report of deaths among the troops in the Philippine service during October shows fourteen from dysentery, one from non-specific diarrhœa, four from typhoid fever, two from malaria, four from Bright's disease, one from tuberculosis, one from tetanus, three from smallpox, two by drowning, three by suicide, seven from the result of wounds, one from alcoholism, and one from accidental bichloride-of-mercury poisoning.

Six Hundred Children a Year Burned to Death in London.—Dr. Westcott, Coroner of Hackney, a suburb of London, has drawn public attention to the terrible yearly record of 600 children burned to death in London. As a result of representations on this subject made by the Coroners' Society to the Home Secretary, the government is considering the advisability of legislation which would enable the coroners to fine and imprison persons who leave children alone with fire, or with material for making a fire, if children are thereby burned to death.—*The Sun.*

War Against Rats at Marseilles.—A dispatch in *The Sun* states that the port authorities of Marseilles have experimented with carbolic acid instead of sulphuric acid in exterminating rats in two ships. The results have been very effective and the carbolic acid has not damaged the cargoes. They hope it may be the means of prevention of plague infections which have hitherto been brought by rats.

A New Medical Society in Montreal.—A petition has been presented to the Quebec authorities for a charter for the Montreal Medico-Chirurgical Society.

Health Department of New York City.—Mayor Low has appointed Ernst J. Lederle Health Commissioner, with Dr. Herman M. Biggs as medical officer, having charge of the medical affairs of the board. Under the provisions of the new charter which takes effect on January 1, the Health Board will consist of the Health Commissioner, the Health Officer, and the Police Commissioner.

Extensive Skin Grafting.—A man was received at the Englewood, N. J., Hospital a few days ago who had been severely burned by an explosion of gas. The denuded surface was of such a great extent that skin grafting was necessitated. The man had served in the Spanish-American war, and his former companions in arms being appealed to, nineteen contributed of their skin for the operation.

New York Red Cross Hospital.—Dr. R. Coleman Kemp has been elected to the position of Attending Physician to Red Cross Hospital, to act in the special department of Experimental Medicine and Hydrotherapeuties for the ensuing fiscal year.

Legacy to the Metropolitan Hospital and Dispensary.—By the will of the late Dr. Henri Guilbault, the Metropolitan Hospital and Dispensary of New York, No. 248 East 82d Street, receives $3,000.

College of Physicians of Philadelphia. Section on General Medicine.—At a stated meeting held December 9, Dr. A. A. Eshner exhibited "A Case of Akromegaly." Dr. Jos. Sailer presented a communication entitled "Demonstration of Some Peculiar Bodies Found in the Peripheral Blood of a Case of Abdominal Tumor Resembling the Parasites of Cancer Described by Gaylord." The conclusion was expressed that these bodies are not parasitic, but in the nature of artefacts resulting from the manipulations to which preparations are subjected. Dr. David Riesman read a paper entitled "Skin

Eruptions in Malaria, with the Report of a Case of Urticaria." He pointed out the relatively frequent occurrence of herpes and urticaria, in conjunction with malaria, referring also to the occurrence of various other cutaneous exanthems in associating with malarial infection. Drs. Wm. M. Welch and Jay F. Schamberg read a paper entitled "A Study of the Initial Symptoms in One Hundred Cases of Smallpox." Attention was called to the frequency with which the disease in its early stages was mistaken for typhoid fever.

A New Kind of "Practitioner."—A woman was sued in a civil court here last week for $90 by a man who claimed the amount for medical services. The man, whose name is Julius A. Ward, calls himself a doctor on the strength of a degree of D.D. which he claims to possess. He also adds the letters M. S. and D. O. to his name in his business. The D. O. stands for diplomat of osteopathy, but the man says he is a somatopath. The definition of somatopathy, as given in the newspaper accounts of Ward's suit, is "the science which, by manipulating and desensitizing the patient, makes possible the correction of physical irregularities or omissions or diseases, due to maladjustments." The defence was that Ward was a quack in the first place, and in the second place, that the woman had agreed that in full exchange for his services to her she would introduce him to her many friends and acquaintances and induce them to patronize him.

Pathological Society of Philadelphia.—At a stated meeting held December 12, Dr. Geo. B. Wood exhibitde sections of "Lacunar Keratosis of the Tonsils" and of "Endothelioma from the Nasal Fossa." Dr. Wm. G. Spiller exhibited a specimen of "Compression of the Brain in a Case of Hyperostosis Cranii," one of "Compression of the Brain from Internal Hemorrhagic Pachymeningitis," and one of "Brain from a Case of Extreme Microcephaly." Dr. A. C. Croftan presented a communication detailing "Some Experiments on the Formation of Bile-pigments and Bile-acids." He showed that trypsin in the presence of hemoglobin and dextrose or other form of physiologic sugar gives rise to the production of the pigment and acids of the bile, and that this function does not belong peculiarly to the cells of the liver. It is the action of trypsin on the sugar in the blood that normally prevents hyperglycemia, and consequently glycosuria. Dr. David L. Edsall read a paper entitled "A Contribution Concerning the Excretion of Sulphur in the Urine," in which he related observations that led to the conclusion that no significance is to be attached to the amount of sulphur eliminated with the urine. Dr. Wm. M. L. Coplin exhibited a specimen of "Secondary Cancer of the Lung (Hematogenous Infection)." The lung was so densely infiltrated with small nodules as to present an appearance suggestive of tuberculosis. Drs. W. M. L. Coplin and D. H. Prince presented the following specimens: (1) Cancer Thrombus in a Branch of the Hepatic Vein, with Infiltration of the Wall; (2) Fatty Cirrhosis of the Liver of a Dog; (3) "Abscess (Chronic) of the Liver; Recrudescence Due to Secondary Infection(?); Thrombosis of the Hepatic Vein and Vena Cava; Extensive Necrosis of the Liver- Hemorrhagic Infarction(?)."

Philadelphia Pediatric Society.—At a stated meeting held December 10, Dr. James K. Young presented a child on whom he had operated for bowlegs by dividing the tibia on each side in its upper third and bending the fibula in position, after which a plaster dressing was applied. Dr S. McC. Hamill presented a case of chronic endocarditis with symptoms of nephritis in a colored child in which marked improvement in symptoms and physical signs followed upon rest in bed, good food, and the administration of small doses of digitalis. Dr. L. C. Peter presented a case of sporadic cretinism in a child seven years old that had been for three years under treatment with thyroid extract and had improved conspicuously. Dr. Peter presented also a case of tumor of the cerebellum in an undersized boy of fifteen with headache, projectile vomiting, impaired vision, atrophic changes in the optic discs, unsteady gait, and variable reflexes. Dr. J. K. Young presented a child three years old in the case of whom recovery had taken place from an attack of epiphysitis of the left femur after incision and drainage. Nominations were made for officers to serve for the ensuing year.

Philadelphia Hospital.—Dr. Geo. M. Boyd has been elected gynecologist to the Philadelphia Hospital, in succession to Dr. G. I. McKelway, previously resigned. The resignation of Dr. R. F. Sommerkamp as Assistant Physician in the Department for the Insane has been accepted. The members of the visiting staff have been re-elected for the year.

Obituary Notes.—Dr. Francis A. Utter died on December 10, at his home in this city. He became ill two days previously, while giving advice to a patient in his office. He was born in this city in 1840 and was graduated from New York University Medical College in 1865. He served as surgeon throughout the Civil War, since which time he had been the official surgeon of Lafayette Post 140. G. A. R.

Dr. William H. Johnson died at his home at Adamstown, Md., on December 13. He was born in 1827, and was graduated from the University of Maryland School of Medicine in 1849.

Dr. Lesslie M. Sweetnam of Toronto died of pyæmia at the Johns Hopkins Hospital, Baltimore, on December 11. Several weeks ago, while cleaning his hands after an operation in the hospital of the University of Toronto he received a small puncture in one of the fingers of his right hand from the nail brush he was using. Blood poisoning set in and he came to the Johns Hopkins Hospital for treatment. He was a graduate of the University of Toronto Faculty of Medicine in 1881. He was professor of clinical surgery in the University of Toronto and associate professor of surgery in the Ontario Medical College for Women. He was also surgeon to the Toronto General and to St. Michael's Hospitals. He was a Fellow of the British Gynecological Society, and a member of numerous local, provincial, and national medical societies.

Dr. J. G. Shoemaker died at Phœnixville, Pa., on December 14, at the age of thirty-six years. He was deputy inspector of the State Board of Health, County Medical Inspector, and one of the Physicians to the Phœnixville Hospital.

Dr. E. S. Leake died at Philadelphia on December 13, at the age of eighty years. He was a graduate of the Medical Department of the University of Pennsylvania.

Population of Great Britain.—According to the official quarterly returns, recently issued, the population of the United Kingdom, in the middle of 1901, is estimated at 41,544,145 persons; England and Wales, 32,617,001; Scotland, 4,483,774; and Ireland, 4,443,370.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING AND HOSPITALS—MEDICAL COUNCIL—PATHOLOGICAL SOCIETY—URINARY SURGERY—BERIBERI—FOOD REPORT—EMBALMING —SMALLPOX.

LONDON, November 20.

THE King has intimated his pleasure that the Prince of Wales' Hospital Fund, from January 1 next, shall be known as King Edward's Hospital Fund for London.

The General Medical Council is sitting—began the session on Tuesday, with the usual dilatation of an agenda paper by the president, concluding with an intimation that he would resign during the session, so as to make his term correspond with that of the period for which he was elected by Edinburgh University. As he has been re-elected for that body, he, no doubt, expects to be again chosen as president. Well, it will be a good precedent, and he is a good chairman, if rather too self-willed and too given to these introductory talks.

The election of direct representatives to the council is going on at the same time. The voting-papers have been posted, and must be returned by the 4th prox., but the poll will not be declared until the 10th prox. Certain formal matters were disposed of and the council sat *in camera* on judicial procedure and decisions. On Wednesday the case of sale of poisons by Scotch practitioners, through unqualified assistants, was pronounced to be "infamous in a professional respect." The degrees of Malta University were agreed to be such as to entitle them to be registered in the colonial list. The report as to Italian degrees was postponed to a later day.

After some discussion on the scientific institutions to be recognized, and indications of the difference between the council and the royal colleges, which may lead to further difficulties, this subject was also postponed by fourteen votes to six.

The council on Thursday was chiefly occupied with penal cases.

What is the difference between the Danysz rat bacillus and the Gaertner bacillus enteritidis? Dr. Klein cannot tell us, but he hesitates to think them identical on account of their different derivation. Both belong to the coli group. They are alike in morphological, cultural, and clumping characteristics, he said at the Pathological Society, where Professor McFadyean and Mr. Foulerton seemed inclined to regard them as identical.

At the same meeting, Professor McFadyean detailed the results of four experiments as to the immunization of cattle against the bacillus tuberculosis, and he agreed with a comment made on his communication by the president (Mr. Watson Cheyne) to the effect that we have no evidence that immunity can be produced in the human subject by tuberculin; its action was to set up inflammation at the sites of infection; if these were small, removal might take place.

In reply to a question, Dr. McFadyean said he did not consider mallein was curative in glanders. The disease was mild in horses, and they recovered from it when they were well kept, though those treated with large doses of mallein withstood large doses of glanders

The Harveian lectures were this year delivered on the 7th, 14th, and 21st of this month, by Mr. Buckston Browne, who took for his subject, "Twenty-five Years' Experience of Urinary Surgery in England." He related some very interesting personal reminiscences, among which may be numbered his association with Sir Henry Thompson. At the end of 1874, Sir Henry invited him to become his assistant, and for fourteen years he worked as such, and since that period by himself, so he has made up his twenty-five years as a private practitioner of urinary surgery. With such an introduction to the specialty, and such an experience, he might well devote his lectures to what he has learned and what he believes in this branch of practice. At the bottom of this lies urinary fever, and with this he began.

The somewhat vague statements of the textbooks are very unsatisfactory, and may be contrasted with the lecturer's clear view and illustrations. He regards it at the outset as suppression of urine due to urethral shock, producing inhibition of the kidneys' action—more or less complete. He deduces the lesson to deal gently with the male urethra, and all will be well; use violence, and disaster will result. This lesson, no doubt, he learned from the first; for Sir H. Thompson has been the great propagandist of the principle of gentleness. It seems that not infrequently Thompson crushed a stone and washed it out at a single sitting, before Professor Bigelow, in 1878, laid that down as a principle of the first importance. Thus Thompson very nearly anticipated Bigelow, and perhaps would have done so altogether but for his respect to the male urethra, his fear of violence preventing him from making the plan his usual practice, though he constantly used Clover's apparatus for evacuating débris.

Clover's name has become so associated with anæsthesia that there are many who have never heard of that apparatus which he described in the *Lancet* in 1866. It is well, therefore, that Mr. B. Browne should have taken the opportunity of doing justice to his ingenuity and resource. He invented a number of things, and among them that apparatus which is the prototype of all subsequent evacuators, and in it lay the germ of modern lithotrity. It is curious, said the lecturer, to note how right Clover was in everything he pointed out from the very beginning, though he never operated for stone; and if he had, he would almost certainly have anticipated Bigelow by some twelve years; instead of that, he handed his apparatus to Sir H. Thompson and turned his attention to anæsthesia. Mr. Browne said sufficient acknowledgment had never been made to Clover, and he pointed out the many proofs that even Bigelow himself had to go back to the principles Clover had laid down

There are three ways of removing a stone from the bladder: (1) Lithotomy; (2) Lithotrity, or crushing and washing out; (3) Washing out whole through a tube. It is the last to which Mr. Browne would apply the term litholapaxy, which merely means carrying away a stone. For Bigelow's operation, lithotrity is sufficient, as his method is the one to be always adopted. Lithotomy cannot be got rid of for some cases. It is the useful partner of the other methods, and Mr. Browne showed when it must be trusted.

On prostatic disease, Mr. Browne spoke more hopefully than of late has been common. He does not admit that in any of these cases a catheter cannot be passed. Naturally, therefore, he is opposed to serious operations, justified by that alleged impossibility. Catheter life is often comfortable and long, provided every care be exercised, and he has known many such persons go on well into the nineties. He has also known a patient, who had depended on a catheter for twelve months, completely recover his natural expulsive power. With this experience he has no good to say of castration or vasectomy, and he offered some grave cautions about prostatectomy. The lecturer holds that the prostate is only a sexual organ and exercises no urinary function whatever, although learned papers have been written on its urinary importance in health, the obvious fact being overlooked that women perform their urinary functions very well without it.

Equally conservative views were expressed on stricture, which largely occupied Mr. Browne in his third and concluding lecture on the 21st inst.

Dr. Patrick Manson delivered an inaugural address before the Epidemiological Society on the 15th inst., taking for subject that *pro tem.* malady, beriberi. If we take the leading feature to be multiple peripheral neuritis, the literature of beriberi shows that other conditions have been included in the name, and the descriptions of epidemics in different localities exhibit no little confusion in nomenclature. It is, therefore, interesting to have Dr. Manson's large experience epitomized. What he understands by beriberi is an epidemic or endemic multiple peripheral neuritis, distinguished from other forms of that condition by proneness to œdema, with implication of the cardiac neuro-muscular system; absence of trophic skin lesions of paresis of muscles of head and neck, of marked implication of the organs of sight, hearing, taste, and smell, and of the mental faculties. Having pointed out other features likely to be present, Dr. Manson mentioned others less constant, and here there seems abundant opportunity for confusion, and difficulty for those who have not had experience in the tropics. Even the lecturer was compelled constantly to reiterate the words, may be. Thus the intensity and duration of the disease may vary within wide limits. It *may be* of a trifling description and a week or two's duration; or it *may be* rapidly fatal, or last for months. The leading feature *may be* paresis and muscular atrophy, or it *may be* extreme anasarca, or it *may be* effusion into pericardium or pleuræ, or it *may be* œdema of the lungs, or it *may be* rapidly fatal paralysis of the right heart or of the diaphragm and respiratory muscles.

These examples of instructive repetitions of may be will suffice to impress the varying features of the disease, and the difficulties which beset the diagnosis, and a similar uncertainty is exhibited on other points in most of the records of the disease. Some of these were considered by Dr. Manson, in whose opinion the etiology and pathology are best referred to an intoxication produced by a toxin formed by a germ, the nidus of which is outside the human body. In this respect it is on all fours with alcoholism, the germ of which is the yeast plant, the nidus solutions of sugar, the toxin alcohol, the pathological effect—peripheral neu-

[illegible] cannot say what the toxin is, what the germ [illegible] germ resides. It clings to people; it clings [illegible] the patient away from the circumstances [illegible] is being poisoned and he begins to recover. [illegible] with alcohol, keep the drink [illegible] and he begins to amend.

T[illegible] of the committee on food has appeared. It [illegible] prohibition of the use of formalin [illegible] of either preservatives [illegible] prohibition [illegible] per cent. of [illegible] butter or margarine [illegible] prohibition of any other preservative in [illegible] prohibition of all preservatives in food [illegible] the [illegible] grain per pound [illegible] salts for [illegible] should not be [illegible]. The [illegible] as to the [illegible].

[illegible] a [illegible] is being given of a mode of embalming by [illegible] vapor. The body is placed in a [illegible] through which air heavily laden with formalin [illegible] by an electric fan. The degree of preservation [illegible] the length of treatment. Three days is [illegible] decay for about a week, and no change is [illegible] month's exposure to the formalin preserves [illegible] indefinite period. There seem plenty of [illegible] for the use of such an apparatus in the [illegible] as on board vessels to avoid burials at sea. The cost is from £80 to £120, but the working expense [illegible] small. It is estimated that a body may be embalmed for about 4s. 6d.

The deaths registered last week in the thirty-three great towns [illegible] a rate of 21 [illegible] per 1,000, against 17.6, 18.7, and [illegible] in the three preceding weeks.

Smallpox still increases in London, from thirteen to sixteen new cases being reported daily. At midnight on Wednesday [illegible] cases were under treatment, and thirteen [illegible] were added yesterday.

COPPER IN THE TREATMENT OF GLAUCOMA.

To the Editor of the Medical Record

SIR: Permit me to reply to the letter of Dr. Williams which appeared in your issue of November 16th, touching upon the use of copper in trachoma. I conceive it to be Dr. Williams' privilege, but not necessarily his duty, to criticise a method of treatment which he considers pernicious, and I would have gladly accorded him the privilege. But I consider it equally my right and hence in my reply I have combated the views he advanced, and condemned the treatment he advocated. He began the discussion, and I have replied. I do not, therefore, see that your correspondent has any cause for complaint. Honors, so far, are even.

Dr. Williams holds that atropine "should be used in every case of conjunctival or corneal affection in which there is photophobia, ciliary spasm, or even excess in lachrymation", and he holds that these conditions are always present in trachoma with ulceration of the cornea. I hold that atropine is *not always* indicated in these conditions, and that the use of atropine in trachoma with ulceration of the cornea, is not only not indicated at times, but seems to be contraindicated; and that the judicious, skillful use of copper alone under these circumstances, is more beneficial than its use in conjunction with atropine. I consider your correspondent's assertion too glitteringly general. Concerning the case of mixed infection, which resulted in perforation of the cornea, to which reference has heretofore been made, I can only say that if I [illegible] his case correctly, the patient had trachoma with ulcers of the cornea. It was treated in New York without atropine, but with peroxide of hydrogen for the ulcers, and likewise copper was applied to the [illegible]. After a month of this "internal" treatment he returned home, and his physician found that he was suffering from iritis, with occlusion of the pupil and ulcer of the cornea, which had perforated. I repeat, I recognize in this history an unfortunate case, which undoubtedly has had its parallel in the hands of many surgeons. I do not believe that the result was caused by the failure to use atropine and the "infernal" treatment he received in New York. I doubt if the use of atropine and the use of your correspondent's weak solutions of silver and copper would have altered the result. It interested me to know that the operation for glaucoma, which supervened, was done by another surgeon than Dr. Williams, but it interests [illegible] to know that the resulting V [illegible] was not in any way attributable to the operation." He remarks further that he himself had supervision of the after-treatment. Does he mean to imply that the operation for glaucoma did not improve the vision at all, and that the [illegible] vision was due to the "infernal" treatment? or does he consider the final result good, and that the V [illegible] was due to his supervision of the after-treatment?

I am glad to have [illegible] your correspondent by reference to Hirschberg's [illegible] concerning the treatment of trachoma with [illegible] solution of silver. He evidently considers Hirschberg's views in line with his own. But I would remind your correspondent that there is a [illegible] between [illegible] to [illegible] grain solution of nitrate of silver and a 1-per-cent. solution. Moreover, I do not think that many, if any, adherents, even of Hirschberg's views can be found in New York, let alone those of your correspondent.

I was quite well aware of Dr. Williams' experience in New York, the instruction which he received, and the colleague with whom he associated. I was, therefore, all the more surprised at his views. But then, I ask no man to swear by the words of his master or his mates. I rather commend originality.

Your correspondent complains and accuses me of misrepresenting him before the public. I am willing to lay this matter before the same tribunal, and abide by their decision. In this connection he says: "I am rather pleased at Dr. Claiborne's astonishment at the cases detailed by me, which must have been profound, or he would not have taken the liberty of misrepresenting what I said. I did not say that the patient R. had been treated by 'six or eight eminent surgeons;' but that he had been treated by 'six or eight men more or less eminent.'" Now, in the name of reason, what is the difference between these expressions, Mr. Editor? If a man is "more eminent" or "less eminent" than another, he is at least *eminent*. The comparative involves the positive. He follows with this parenthetical sentence: ("I think that the gentleman was not treated in New York, or I should not have called attention to the correction.") I do not grasp the meaning of this apocryphal parenthesis. I plead "Not Guilty" to this specification.

Your correspondent continues: "Further, I did not say that I had cured this patient completely in three months, or in any other time; but that, under the treatment outlined above, he was immediately relieved and able in three weeks to return to his work, using the bichloride at home: in three months the eyes were practically well, and have remained so now twelve years."

Now, Mr. Editor, let us dissect this matter, and render justice. Your correspondent claims that he did not say that he cured this patient completely in three months or *any other time* (italics my own, J. H. C.); yet, by his own words, correctly quoted above, he says, the eyes were *practically well* in three months, and have remained so for twelve years, presumably up to the time of writing. If a case has got practically well in three months, and remained so for twelve years without recrudescence, I think it reasonable to pronounce it cured.

If, however, in any slight way I have rendered your correspondent injustice I hasten to express my regret, to disclaim any intention of so doing, and to leave my justification in the hands of the tribunal selected by your correspondent.

The emotion which I have heretofore admitted on reading his views finds its climax in the following quotation from his letter: "Dr. Claiborne will never see a cure of trachoma effected in any other way, whatever the treatment used." I would say here, in the interests of the younger men, to whom we have both appealed, that I have seen cases of trachoma cured by copper alone, and by the use of "expression" followed by a course of copper.

Your correspondent continues: "I regret that the opportunity may not be mine of demonstrating to Dr. Claiborne, at first hand, the efficacy of the method of treatment which has made such a shocking impression on his mind; but if the doctor is inclined to play fair, and really is in earnest, I now ask him to give the plan an honest trial, and report his results as honestly."

Now, Mr. Editor, I fancy I shall be forgiven if I do not permit any one to cram down my throat views that are contrary to my teaching, my experience, and my sense. I am willing to learn anything from anybody, and I do not deny specifically anything that I have not seen disproved; but I cannot permit myself to depart from the ways of experience and reason

to waste time and energy in following what I believe to be a therapeutic will-o'-the-wisp.

In case I do not accede to the request he makes, he hands me the following alternative: "If he declines this gambit (*sic*), then I name him a slave to the copper jade, a victim of cuprous hemianopsia, and afflicted with psychic pseudo-scientific myopia, and that he keep his peace." I would point out to your correspondent that in these words he has dropped the light sword of debate with which he has heretofore afforded me some amusement, and makes an awkward attempt to use the bludgeon. I would point out to him, also, that he has used what in logic is called the [illegible] *ad hominem*, which is not regarded as ethical in [illegible], is not relevant to the subject, and is usually [illegible] as a sign of spiritual perturbation, and the [illegible] of disintegration and defeat. From a scientific standpoint it can only be described as *twaddle*.

J. H. CLAIBORNE, M.D.

30 WEST THIRTY-SIXTH STREET, NEW YORK CITY.

BORDERLAND BETWEEN MEDICINE AND SURGERY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of December 7, 1901, contains a very interesting article by Dr. George Woolsey of New York City entitled "Some Observations on the Borderland Between Medicine and Surgery." So far as the same subjects are treated, this is in accord with articles of mine on the co-operation of physician and surgeon in abdominal practice appearing in *International Clinics* in January, 1900, and in the *International Medical Magazine* in June, 1900. But, with all respect to Dr. Woolsey, it is high time that a protest should be made against the surgical dictum that, in all cases of appendicitis, the surgeon should be called in to confirm the diagnosis and to decide when to operate. I make no allusion to instances in which the attending physician is inexperienced, nor to those cases which present peculiar and puzzling features and which suggest a number of consultants in the hope that some one's experience will fit the case in question. With these exceptions, I would submit the following propositions regarding appendicitis:

1. The great majority of cases to which the term appendicitis may be applied are essentially typhlitides with or without a local lesion of the appendix.

2. Unless there is a septic or gangrenous process or reasonable danger of such a condition, mild acute cases should not be submitted to operation, but should be treated medically.

3. Chronic inflammations should be treated medically unless there is great or irregular enlargement, or unless the result of a few weeks' treatment is unfavorable. An exception should also be made in favor of patients who wish the operation as a sort of insurance, especially if their residence is at a distance from skilled medical and surgical attendance.

4. Relapses should not be regarded as significant unless they occur with increasing severity and after rational treatment. The morphine or opium treatment is really no treatment at all; it simply keeps the patient comfortable while he runs his chances of a spontaneous cure. It may favor the formation of protective adhesions, but it is certainly not reliable for this purpose and, anyhow, the case that needs adhesions requires operation much more. It is unreasonable to suppose that a case should not relapse unless something is done to prevent it by proper care during the remission of acute symptoms. Even after the extirpation of an appendix, the case should be remanded to the medical practitioner for treatment of the typhlitis that almost always remains. Several patients have consulted me for "relapses" after operation by careful and thorough operators.

5. It is the duty, not of the surgeon, but of the physician, to make the diagnosis, and to decide whether operation is necessary, and, if so, when it shall be performed.

Very truly yours,

A. L. BENEDICT, M.D.

BUFFALO, N. Y., December 11.

A Bacteriological Study of Dissecting-Room Cadavers.—Nathaniel Gildersleeve discovered living, infective organisms (B. tuberculosis and staphylococcus pyogenes aureus) in bodies which had been properly embalmed, and had remained as long as six months in the cold-storage vault. The pus organisms were in the majority of cases virulent. Such evidence leaves no doubt as to the advisability of careful precautions against infection during practical work in the dissecting room.—*University of Pennsylvania Medical Bulletin.*

THE INJECTION OF SOLIDIFYING OILS INTO THE TISSUES FOR NEURO-MECHANICAL PURPOSES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I note with peculiar interest the letter of Dr. Eugene H. Eising on "Cosmetic Surgery," contained in the MEDICAL RECORD of December 7.

The "Cosmetic Surgery" to which he draws attention, and which is now stirring the interest of medical circles in Vienna, consists in the subcutaneous injection of a preparation of paraffin over bony excavations which have resulted either after operation or from disease, or from congenital causes.

What is the [illegible] dressed [illegible] in European [illegible] and [illegible] its birth to dazzle the [illegible]?

As long ago as 1894, in the [illegible] *Journal* of April 14, 1894, Dr. J. L. Corning of New York practised the injection of [illegible] paraffin and cocoa butter in cases of localized muscular spasm. Thus, in a case of severe torticollis occurring in the writer's own practice, where the chronic convulsive condition was largely limited to the splenius [illegible], Dr. Corning resorted to this expedient, injecting a solidified mass of cocoa butter and paraffin into the affected muscle in such fashion as to completely prevent its contraction. The melting point of the injected [illegible] was several degrees above that of the blood temperature; and the precipitation of the same was brought about *instantly* after injection—a most important point in the prevention of oil embolism—by throwing a spray of ether upon the injected region. Gersuny and other imitators of Corning would have done better, had they retained this principle so scientifically conceived by our distinguished countryman.

It only remains to add that the patient is still living; that he still carries around in his muscle a considerable quantity of the solidified oil—long since incapsulated, no doubt—and that his spasm has been cured, although I must confess that he occasionally suffers pain. When I recall the fact that this patient's debility and suffering were so great as to render him suicidal, I feel that the result achieved was remarkable. May not the profession hope that the proverbial sense of justice of the distinguished editor of the MEDICAL RECORD will see that due credit is awarded in this matter?

MORTIMER LAMPSON, M.D.

SURGEON ST. FRANCIS HOSPITAL, JERSEY CITY, N. J.

"SANATORIUM" VS. "HOSPITAL FOR INCIPIENTS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In to-day's MEDICAL RECORD appeared the admirable address, entitled "Municipal Sanatoria," which was delivered by Dr. Alfred Meyer, before the Second New York State Conference of Charities, on November 21. I had the honor of opening the discussion on Dr. Meyer's paper, and, like any one in sympathy with this movement, was happy to have an opportunity to endorse the many strong and telling arguments brought forth by Dr. Meyer in favor of the consumptive poor, and to express to him my gratitude for his ceaseless energy, his enthusiasm, and the wide knowledge which he has displayed in pleading so just, so urgent, and so noble a cause.

There is, however, one point in the paper on which I took issue with Dr. Meyer at the time when he read it. I take issue again, now that it has appeared in print, to make it possible to get also the expression of opinion of other minds on the subject.

To make my point clear I may be permitted to reproduce here a few sentences of the address. On page 930 of the RECORD, Dr. Meyer says: "As a final outcome (of a meeting of the Academy of Medicine), a committee of five physicians, of whom I am one, was appointed by the council to co-operate with other bodies to further the erection of a municipal hospital for consumptives, and the following resolutions were adopted, which may well be accepted as a most excellent enunciation of principles for all similar institutions.

"First. Resolved, That the Committee appointed by the Academy be instructed to use its influence to have the municipal hospital constructed for cases in the early and presumably curable stage of phthisis.

"Second. Resolved, That while the proper designation for such a hospital would be for curable cases, yet, in view of the bad effect a refusal to be admitted would produce upon others, the designation be 'Hospital for Incipients.'"

At the State Charity Conference I criticised the expression "Hospital for Incipients" and protested against the use of these words. I think it is a very unfortunate name.

It does not hide anything. The average American citizen is intelligent enough to know what incipient means, and if he does not, he will look it up in his dictionary. It means, beginning, commencement or belonging to the first stage; and he knows that if he is not received in that institution with the peculiar name, it is because he is no longer in the first stage. I would much prefer the simple word "Sanatorium," whether in the city or country, belonging to the municipality or to the State. There is a charm in this word. The average patient will think it vastly better than hospital. If he should look it up in his dictionary it will reveal to him the fact that the word "sanatorium" is derived from *sanare*, to heal, and that that means an institution for healing disease—"Heilanstalt." New hope will enter into the often depressed spirit of the patient; by being received in a sanatorium he will think and feel that he has another chance for life. The word "sanatorium" is in my humble opinion more appropriate than "sanitarium," from *sanitas*, health, employed in this country usually to designate a place as especially healthy, a favorite resort for convalescent patients, or an institution for the treatment of nervous diseases or mental disorders.

Dr. Meyer is so enthusiastic over the words "Hospital for Incipients" as a name for the place for curable cases of phthisis, that he desires all similar institutions to accept the name. I sincerely hope this may not be done. The first public institution established for the treatment of incipient tuberculosis patients is the one at Rutland, Mass. It was formerly called "State Hospital for Tuberculous Patients." I had the gratification of seeing this name changed into simple "Sanatorium." The U. S. Marine Hospital has adopted the word "sanatorium" in preference to the word "sanitarium" for its Fort Stanton hospital for the treatment of consumptive sailors.

I have made this criticism in the spirit of kindness and hope that Dr. Meyer and his colleagues on the Committee will accept it in the same spirit. The Committee of the Academy of Medicine has done most excellent work in bringing the need of a municipal sanatorium before the New York public. Thanks to this committee and to the State Tuberculosis Commission the sanatorium movement has received a strong impetus, and I desire to repeat here what I said at the Charity Conference in reference to the two greatest workers in the anti-tuberculosis crusade in the State of New York: When our State sanatorium will at last be established, it will be largely due to the effort of Dr. Pryor of Buffalo, and if our city sanatorium should see the light of day, which we hope will be very soon, it will be largely due to the efforts of Dr. Alfred Meyer.

S. A. KNOPF, M.D.
19 WEST NINETY FIFTH STREET.

Prognosis in Neuritis.—F. Savary Pearce says that pressure neuritis, the result of a continued pressure of some consecutive hours, will, as a rule, be cured with the use of galvanism and massage within two to three months. Alcoholism makes the prognosis worse. Relapses may occur. Degeneration of peripheral nerve trunks after severance is usually grave as to prognosis, unless the operation of suturing is done. Septic cases of neuritis are usually favorable, if of interstitial type, and will subside under treatment within a few weeks after the primal seat of infection has been eradicated. Alcoholic neuritis is most difficult to prognosticate; first attacks are usually recovered from in a year or eighteen months under careful treatment. Neuritis from lead or mercury poisoning may leave local palsies and tendencies to relapse. Neuritis from diphtheria is apt to be fulgurant and more severe when antitoxin has been used. To reach neuritis due to gastro-intestinal disorders or the gouty or rheumatic diathesis, the original disease must be treated. *Transylvania Medical Journal.*

Is It Advisable to Await Reaction from Shock in Severe Injuries Before Operating?—M. F. PORTER says that anæsthesia is the best remedy known with which to combat the nervous element in shock, that direct intravenous transfusion of normal saline solution is the best remedy in hemorrhage; that delay in operating increases the danger from sepsis. Therefore, he thinks, we should be governed by reason, rather than by rule, in these cases and operate at once and transfuse under anæsthesia rather than wait and waste time that is precious to our patients, by adhering to traditional teaching through fear of the fetish of authority. *Fort Wayne Medical Journal.*

Progress of Medical Science.

Boston Medical and Surgical Journal, December 12, 1901.

Use of Antistreptococcus Serum in a Case of Septicæmia Following Mastoid Operation; Recovery.—Mary F. Hobart reports the case of a woman of sixty-three years who developed septicæmia after mastoid operation. Dr. Shattuck, called in consultation, considered the case all but hopeless, and suggested the serum as a last resort. Temperature was 105.2°, pulse 122. Owing to a fault in technique only 3 c.c. of serum were injected, but two hours later 10 c.c. All the symptoms became exaggerated, but after about five hours there was slight improvement. Erysipelas developed in the wound, and the pus was loaded with streptococci. The next day a second dose of serum was injected; the patient's condition again seemed hopeless, but the following day there was a slight change for the better, and the reaction after the dose was less marked. Recovery set in, and four days after the first injection of antitoxin the temperature was normal all day, and the pulse was 84 to 90. Three weeks later the patient was convalescent.

Twelve Cases of Pneumonia Treated by Antipneumococcus Serum.—George G. Sears says that the cases treated were unsatisfactory for experimentation, as six of the patients were alcoholics, two had mitral regurgitation, two nephritis, and one arteriosclerosis, while another was pregnant and had pericarditis. Three patients died. In the nine recoveries the temperature returned to normal at about the usual time, so that the only conclusion to be drawn is that the course is not lengthened. The serum is certainly no specific against the pain resulting from the inflamed pleura, yet in some cases it gave relief. The fever was not markedly affected; while distinct benefit may not be positively ascribed to the serum, no ill effects, beyond what may occur from the use of diphtheria antitoxin, were observed. However, the results obtained, considering the unsatisfactory nature of the material, seem to justify a further trial of this form of treatment. Greater success might have been obtained if it had been begun earlier in the disease, as it was given before the third day in but four cases.

Massage and Movements in Hemiplegia.—Douglas Graham says that in cases of paralysis, in the absence of severe pain, obstinate contraction, or tonic spasms, massage has been found useful in improving the circulation, reducing temperature, and producing comfort of the parts affected. When the causative conditions have ceased, paralyzed muscles will not at once resume their former natural condition. Massage and passive and resistive movements restore them to a sense of existence, enable them to recognize the power they still possess, and educate this to a higher degree; and at the same time such treatment affords the only means of judging of the capabilities of the patient, and of telling him how to use them. Sometimes the patient will make better motion against resistance than without it. Interlocking the fingers of one hand with the other, so that the well arm can raise the paralyzed one, is a most excellent device, encourages the patient, and educates the unimpaired centers to supplement the deficiency of the injured ones. This should be repeated regularly, six to twelve times, three times a day. The author reports several cases.

Journal of the American Medical Association, Dec. 14, 1901.

Rhinoscleroma.—C. W. Allen reports two cases of the affection so rare in America. One was in a woman from Hungary and the other in a man from Galicia. The report is accompanied by some excellent photographs. In the first case, there was, contrary to the statement given by several writers, a considerable sloughing of the affected tissues. In view of the fact that the disease does not confine itself to the nose when once its course has begun, Allen prefers the term "glioscleroma," suggested by Kaposi.

Complete Recovery from Double Neuroretinitis in a Case of Prolonged Hæmaturia, with Symptoms of Bright's Disease.—The patient of C. A. Veasey was a woman of thirty-five years, who had passed bloody urine without known cause, had lost flesh, was weak and pale, with vertigo, dyspnœa, tinnitus, and intense constant headache. Systematic examination revealed the presence of Bright's disease. Under milk diet and Basham's mixture recovery was steady, though slow, until at the expiration of nine months from the time at which the eyes were first examined, the ophthalmoscope revealed no intraocular changes. The nerves were healthy in appearance and normal in color, the edges well defined, the vessels were unchanged, and there were no traces of the minute hemorrhages previously noted, the macular regions giving absolutely no indications of the previously existing conditions. Vision in each eye equaled 6/6, and the fields

were normal. From a study of the symptoms and course of the affection, the most plausible explanation seems to be that the patient at first had an acute inflammation of the kidneys, which ran into a chronic state, at the expiration of eight months, producing the intraocular lesions previously described. What bearing the hematuria had upon the condition, whether it was a factor in the production of the nephritis or *vice versa*, or occurred merely as a coincidence, can only be surmised.

The Value of the Excision of the Superior Cervical Sympathetic Ganglion in Glaucoma.—The conclusions of G. F. Suker are as follows: (1) Sympathectomy is a justifiable operation. (2) Though the excised ganglion shows changes, yet the true relationship between it and glaucoma is an open question. (3) It is not the *sine qua non*, but a most valuable adjunctive procedure. (4) It is always indicated when an iridectomy or sclerotomy in any form of glaucoma has failed. (5) Iridectomy is still the classical treatment for certain forms of glaucoma, *i. e.* chronic and acute. (6) It is the preferable procedure in glaucoma absolutum and hemorrhagicum. (7) Operate only on one side—affected side. (8) Employ the suitable medicinal treatment after the operation. (9) Do not extirpate the ganglion in acute inflammatory forms of glaucoma. (10) There probably is a close connection between the ciliary, superior cervical sympathetic, and glaucoma. What it is, experiments will show. (11) Extirpation of the ganglion is indicated whenever there is increased tension not controlled by any other measure. (12) The results depend in a great measure upon the condition of the case. (13) Primary extirpation may have to be followed by an iridectomy. (14) It is indicated in those cases of glaucoma which already have extremely poor vision and where any interference with the eye proper might result unfavorably. (15) It is to be considered at all times when other operative measures are refused, irrespective of the form of glaucoma. (16) The excision of this ganglion has varying effects upon the fundus oculi—none detrimental, however.

The Rôle of Mast-Cells in Acute and Chronic Affections.—H. U. Williams reviews the literature of this subject. He says that mast-cells are uncommon in pus and in mucopurulent discharges. Although it does not appear that any special search has been made for them in acute infectious diseases, the histologies of the infections have been so carefully worked out that they could certainly not have been overlooked. Upon reading recent studies of acute affections of all sorts, one finds that while mast-cells are frequently present in and around he lesions, they have not been seen in such numbers or so arranged that any specific relation has been ascribed to them. In chronic infectious diseases, especially tuberculosis, mast-cells are usually present in the zone of reactive inflammation about the lesions, where they may be numerous. The lesions themselves do not contain them in large numbers, if at all. There is nothing to show that the infectious element causes this increase. It appears from the preceding that evidence is at present lacking to prove that mast-cells have any special relation to infections in general or to any particular infection. But it must be said that the subject has not yet received the study that it deserves. The facility with which these cells may be demonstrated, the large size of their granules, and the exhibition of characteristic reactions by the granules make them a promising field for research. In general, Williams believes that where mast-cells become increased, plasma-cells are likely to be present and in much larger numbers than the mast-cells. This parallelism is not close, however. The writer's impression is that plasma-cells appear to be more definitely connected with infectious processes than mast-cells.

New York Medical Journal, December 14, 1901.

Mycosis of the Tonsil and Base of the Tongue.—E. H. Griffin reports a case occurring in a woman of twenty-four years, the growth being unusually abundant and heavy. Cure resulted from having the patient smoke tobacco, from cauterization with chromic acid, evulsion of the deposits with forceps, and a gargle of iron tincture in glycerin.

Hysterical Dissociation of Temperature Senses with Reversal of Sensibility to Cold.—G. W. McCaskey reports the case of a man of forty-two years in whom there was a functional involvement of the sensory centers concerned in the reception of the sensations of pain and cold—the former being impaired and the latter "reversed" and morbidly acute. The patient complained of weakness, especially in the lower extremities, pain in the back (lumbar region), impaired appetite, troubled sleep, and "dizzy staggering spells." There was also complete loss of sexual power and, at times, difficult urination, *i. e.* difficulty in starting the flow of urine. There was profound malnutrition. Tactile sensation and the perception of warmth were found to be perfectly normal throughout the body. The pain sense was absent over the entire area of the lower extremities. The result of the test for thermal sensation was, however, entirely unique in the author's experience. Two large test tubes, eight inches long and one inch in diameter, were filled with hot and cold water respectively and applied to the skin, the patient's eyes being closed. As already stated, the perception of warmth was entirely normal. Different degrees of heat were correctly recognized without hesitation. But when the tube of cold water was applied to the skin, he invariably said it was hot; and the colder the water, the more he would flinch from the sensation of "heat." If the tube contained iced water, he would very nearly jump off the table. If, on the contrary, it was 55° or 60° F., he would simply designate it as hot or warm. No cold impression was recognized as such anywhere, except over the face and neck. The character and distribution of the sensory disturbance at once pointed to hysteria, although there was nothing in the history of the case indicating that condition.

Laryngeal Paralyses and Their Importance in General Medicine.—J. W. Gleitsmann gives a review of our present knowledge of the nerve supply of the larynx and of the centers governing this organ. The prototype of cortical paralysis is seen in hysterical aphonia in which the muscles subject to the will (*i. e.* the adductors and their adjuvants) do not respond to attempted voice production, but in many cases retain their function for reflex acts, such as coughing, crying from pain and during sleep, with ability to sing, but not to talk. Certain sexual events, psychical influences, direct trauma, reflex action as from adenoids or nasal polypi may also cause lateral adductor paralysis. All the lesions enumerated produce bilateral paralysis. Cortical paralysis may also follow symmetrical tumors, syphilis, tuberculosis, softening, etc. Paralyses of the pneumogastric, recurrent, and posticus nerves vary in appearance according to the exact site on the nerve at which the disturbing cause acts. Organic causes may either be from the bulb and spinal column or of peripheral origin. The former include softening processes, hemorrhages, syphilis, tumors, diphtheria, progressive bulbar paralysis, amyotrophic lateral sclerosis, syringomyelia, and tabes. Peripheral causes are tumors of the neck, aneurysm of the aorta, innominate, or right subclavian, mediastinal tumors, enlarged peribronchial glands, pericarditis, pleuritic adhesions, trauma, infectious diseases, influenza, scarlatina, typhoid fever, toxic influences (lead), or rheumatism. These latter act by causing a peripheral neuritis. The importance of bearing all these possibilities in mind arises from the fact that an abductor paralysis may antedate all the usual symptoms of locomotor ataxia, and one cord in the median line may be the only danger signal of an incipient aneurysm. Another equally important point for practical medicine consists in the absence of any laryngeal subjective symptom in many cases in which only unilateral abductor paresis is present. It does not produce dyspnœa under ordinary circumstances or any alteration of the voice, as a perfect approximation of the cords takes place in phonation, and to the patient himself his serious condition is unknown. Hence in all doubtful and obscure cases a thorough examination of the larynx is just as necessary as is an examination of the urine.

Medical News, December 14, 1901.

Rectocolitis.—William M. Beach concludes that: (1) Rectocolitis is a condition of the rectum and colon of varying degrees of inflammation; (2) A knowledge of the anatomical bearings of the rectum and colon is necessary to understand the symptoms and reflexes; (3) The symptoms are local and systemic; (4) Rectocolitis may be catarrhal or ulcerative; (5) It may be acute or chronic; (6) When dependent upon polypus, hemorrhoids, fistula, etc., the cure depends upon their removal; (7) Chronic rectocolitis due to altered secretions, anemia, and congenital narrowing of the sigmoid strait is difficult to cure.

Clinical Facts and Their Meaning.—Joseph M. Aiken believes that the physician in his everyday practice sees more cases classed as nervous than the sum of his cases in any other two departments of medicine. The writer calls attention to the large number of cases which are ill because of faulty digestion or assimilation. The variety and degree of gain and nervous disorder consequent on acute gastric indigestion are generally conceded as sufficient cause for great prostration. At least 80 per cent of our population have faulty digestion, and of these 75 per cent. are gastro-intestinal, principally the latter. A large percentage of the neurotic cases are of purely functional origin. However, rational therapeutics are necessary here. When the alimentary canal refuses to assimilate natural ingesta, the overworked organs must

to the rest. Liquid diet should be given, and as far as possible all food should be hot for its stimulating effect. Nourishment in atonic dyspeptic cases should be given every two or three hours.

Philadelphia Medical Journal, December 14, 1901

The Operative Treatment of Intercostal Neuralgia Occurring in the Deformities of the Chest Following Pott's Disease and Scoliosis.—Charles F. Painter discusses the technique of this operation as simply that of an excision of the rib; the point of election at which to operate is not decided with a view of finding the particular nerve trunk to be acted upon, but to remove sufficient bone to give the other ribs more room. It may be, of course, that several ribs is chosen which is causing the pressure upon the intercostal.

Penetrating Wounds of the Heart, with Suturing of the Wounds.—H. L. Nietert has collected 72 consecutive cases of penetrating wounds of the heart, where suturing was performed. In this number is included his own case. Out of these seventy-three patients, sixteen died and seven recovered. In twenty-one cases, the wound was located on the left side of the sternum, in two cases on the right side. The pleura was injured in twenty two cases, and uninjured in one case. The left auricle was penetrated in one case, the right ventricle in six cases, the left ventricle in fifteen cases. The writer is persuaded that, in the future, operations on the heart for penetrating wounds will be more frequently performed. Statistics show that more than 90 per cent. of all heart wounds not operated upon prove fatal. The mortality in the cases collected, although these are among the most serious of heart wounds, is only 70 per cent.

The Division of the Sensory Root of the Trigeminus for the Relief of Tic Douloureux.—William G. Spiller and Charles H. Frazier recommend as a substitute for all operations which depend for their success upon removal of all or part of the ganglion, an operation which depends for its success solely upon the division of the sensory root of the ganglion. Granting that it would effect a radical and permanent cure, the advantages of this operation would be: (1) It should be attended with a lower mortality; (2) It should obviate a number of difficulties; (3) Its execution would be, comparatively speaking, simple; (4) It would be practically complete when the posterior aspect of the ganglion and its sensory root have been exposed; that is, it would be practically complete before the most serious and troublesome difficulties common to other operations would have been encountered; (5) The integrity of the cavernous sinus would never be in danger; (6) The risk of injuring the sixth nerve would be avoided.

American Medicine, December 14, 1901.

Formalin as a Disinfectant for the Hands; An Unpleasant Personal Experience.—Charles P. Noble reports an experience with formalin which shows the danger of prolonged contact with formalin. After using formalin for about a month, his hands were attacked by such a violent inflammation that serum formed under the nails, separating them from the underlying tissue. Under the influence of rest and elevation of the parts, together with an ointment of ichthyol, the inflammation subsided without suppuration. On the two days preceding the attack, rubber gloves had been worn for four hours each day. The gloves had been filled with formalin, and enough of the solution was left inside the gloves to keep the finger ends moistened while the gloves were worn.

What Protection Have the People Against the Dairy?—D. M. McMasters says that, so far as laws made for the protection of food are concerned, milk, which is a universal food, has less protection than any other. Nothing absorbs impurities more rapidly than does milk. The writer believes that it is proven beyond doubt that that transmission of tuberculosis from man to animal and animal to man is an assured fact. He is convinced that tuberculosis can be transmitted through milk. Dairymen should be impressed with the fact that the number of bacteria in milk depends upon four things: (1) The original amount of germicidal substance in the milk over which they have no control; (2) The number of bacteria falling in during the milking or afterward; (3) The length of time which has passed since milking; (4) The temperature at which it is kept. This subject is now with the medical profession, boards of health, the dairymen, and the people. The harmonious working of all these factors can so reduce the bacterial army that its power for destruction will be reduced to a minimum.

The Relation of Appendicitis to Infectious Diseases.—J. M. T. Finney and Louis P. Hamburger declare that every variety of appendicitis is to-day essentially a surgical disease. For purposes of treatment this disease is rightly regarded as a local disease subject to serious accidents readily explained by anatomic and bacteriologic factors. The diseased appendix is a source of danger to the peritoneum and thus to the life of the patient. When it is removed the danger is averted. According to M. Reclus, there is a kind of appendicitis called "propagated appendicitis"—appendicitis which results from the extension of inflammation from the neighboring intestinal mucosa, a sequel or an accompaniment of an enterocolitis. Cases have been noted of appendicitis associated with arthritis. These cases call attention to the form of appendicitis which may be the local expression of a general infection. There seems now and then to be a close relation between polyarthritis and appendicitis. The articular disease may precede as well as accompany or follow the inflammation of the appendix.

The Lancet, December 7, 1901.

Acute Emphysematous Gangrene.—N. H. Choksy gives the details of treatment in four cases seen in the course of the last two years. He confirms the statements of Welch and others that tissues damaged by the injection of bacterial toxins are prone to irritation by the gas bacillus and that even the most unirritating solutions injected hypodermically are at times followed by such infection. He believes that in view of the fact that so many injections have been made during the last few years in cholera, the plague, etc., gaseous abscesses are surprisingly few and that the infection when occurring has probably been conveyed by the needles used for the injections, from the skin of the patients.

A Few Words on Headaches of Nasal Origin.—A. Bronner believes that headaches are often due to diseases of the nose and its accessory sinuses. Nasal headache is often of a neuralgic character and is then generally caused by sinus disease. It is generally supraorbital or localized in the middle of the head behind the eyes or at the top of the head. It is usually intermittent, often very severe, and it comes on at certain fixed periods, but is always worse in the morning. A diffuse headache may be due to nasal obstruction or rhinitis. The head symptoms due to sinus disease are not characteristic or confined to any special area. Antrum trouble may cause pain in the cheek or frontal region. Frontal sinus disease causes local pain increased on pressure. It radiates into the head and is often worse over the sinus of the opposite side. The pain is intermittent and worse in the morning. It is increased by any sudden movement. The pain from ethmoidal disease is not typical or severe. It is chiefly confined to the nose and radiates backward. Affections of the anterior ethmoidal cells simulate frontal sinus disease; those of the middle or posterior ethmoidal cells simulate sphenoidal trouble. The latter is generally not diagnosed. There is usually intense pain in the middle of the head behind the eyes. It is intermittent and may be absent for days or weeks. There are frequent attacks of giddiness and the head feels as if it was going to burst. Illustrative cases are given.

Pure Urea in the Treatment of Tuberculosis.—Seven cases of the disease are reported by Henry Harper, who believes that urea exerts a specific action on tuberculosis quite as marked as mercury on a syphilitic node, salicylate of soda in rheumatism, or iodide of potassium in bronchial asthma. Cases suitable for the administration of urea are (1) Circumscribed pulmonary tuberculosis of the lung, in which the sputum exhibits abundance of bacilli and only a limited number of cocci; (2) Enlarged tuberculous glands situated on any part of the body; (3) Tuberculous pleurisy (here in my cases urea acted like magic); (4) Tuberculous laryngitis; (5) Lupus; (6) Tuberculosis of the peritoneum with fluid in the peritoneal cavity; (7) Hydrocephalus in children; and (8) Tabes mesenterica or carreau. Cases which are unsuitable are: (1) Pulmonary tuberculosis in which cocci predominate, practically covering the whole field of the microscope, and the tubercle bacilli exhibit a short, stumpy appearance, the typical Koch bacillus being scanty; (2) Acute miliary tuberculosis with a high temperature (103° F. or over); (3) Gastritis; (4) The last stage of tuberculosis when the patient is dying; and (5) When the patient has a temperature over 101°. To carry out the intensified method, a beginning should be made with small doses of from 10 to 15 grains thrice daily, gradually increasing them up to 40, 50, or 60 grains as a maximum. Practically this amounts to one-half per cent. of artificial urea added to the normal quantity circulating in the blood.

Excess of Salt in the Diet a Probable Factor in the Causation of Cancer.—From a statistical study of the dietetic peculiarities of certain districts and of the occurrence therein of cancer, J. Braithwaite favors the view that the excess of salt in the diet has a bearing on the etiology of this malady. He believes that this excess of salt is one of the four factors which originate it. This

is the essential factor, he says, but it is inoperative without at least one, and probably two, of the others. Excess of salts may arise from individual taste, or from much salt meat, or from too much ordinary meat, which of course involves much salt. The other factors are these: (2) An over-nourished condition of body from more food, and especially more meat, than is required. This condition is rarely met with amongst out-of-door manual workers; (3) An impure condition of body owing to non-use and non-oxidation of the food which has been taken. The amount may have been moderate or even small. The cells of the body in this condition are loaded with effete material. It obtains in old age; in persons who lead indolent, easy, and indoor lives; and locally in organs the active functions of which have ceased. (4) A fourth factor is some local irritant or stimulant, such as friction from the stem of a pipe or irritation from some microorganism of which no one is actually specific, or ovarian stimulation in the case of the breast. Of these the first must always be present, and probably in some form the fourth and also in all either the second or the third, but not both of them. Confirmatory evidence is also afforded from the fact that cancer is practically unknown among animals that do not use salt

Three Cases of Family Periodic Paralysis, with a Consideration of the Pathology of the Disease.—The cases are reported by E. F. Buzzard, the patients being a woman and her two sons, aged respectively eleven and thirteen years. Concerning the pathology of the affection, he reviews the various theories of the nature of the disease, calling attention to the fact that all writers have assumed a toxic origin for the disease, while many have pinned their faith to a theory of autointoxication. Buzzard himself inclines to the view that the muscular substance itself is the seat of some temporary change profound enough to prevent it from carrying out its normal function, that of contraction, under any form of stimulation. The fact that this change follows muscular activity, but is only consummated during periods of muscular rest, leads one to consider what part may be played by the lymphatic circulation in the production of this change. We know that the lymph-flow is influenced chiefly by three factors: (1) The difference between the intra-capillary blood-pressure and the extra-capillary pressure in the lymph spaces of the surrounding tissues; and (2) The influence of muscular contractions in conjunction with (3) The presence of valves in the lymphatic vessels. The first factor suggests that the production of lymph in the muscle tissue will be increased by the activity of the muscles. The second factor suggests that during muscular inactivity a most important agent in the removal of this lymph is not at work. Two questions naturally present themselves: (1) Is it possible that conditions may arise when, in the absence of muscular contraction, the other factors in the removal of lymph may be insufficient for the purpose and so lead to a form of stagnation in the lymph-spaces of muscle tissue? (2) Can the lymph in such circumstances cause some physical or chemical change in the muscle plasma sufficient to reduce or temporarily to destroy its contractility? These possibilities nearly assume the proportions of probabilities when the clinical phenomena of the disease are examined by their light. In conclusion, Buzzard calls attention to two points he deems worthy of careful consideration: (1) That a chemical or physical change in the muscle plasma alone is not only a possible, but the probable, explanation of the loss of contractility described in this disease. (2) That the important part played by the muscular system in the control of the lymph circulation points to an unstable condition of the latter or an abnormal, perhaps toxic, constituent of the fluid itself as possible sources for the changes in the muscles.

British Medical Journal, December 7, 1901.

Rectal Serum Therapy.—E. Wolfenden Collins was called to attend a glycosuric patient for an attack of erysipelas. He first washed out the bowel with hot water, after which he injected from an ordinary glass syringe, through a catheter, high up into the rectum, 10 c.c. of anti-streptococcus serum. Four hours later there was a decided improvement in the patient. The next morning this treatment was repeated, and two hours later the patient was walking around the room. The further progress was perfectly satisfactory.

Paroxysmal Dyspnœa in Aneurysm of the Arch of the Aorta.—F. Bushnell refers to a case in which the patient became acutely orthopnœic, cyanosed, and rapidly unconscious. Tracheotomy was performed though the cause of the spasms of the ordinary and extraordinary muscles of respiration continued. Dyspnœa was uncertain, but the patient was only slightly relieved, and lived two days. Necropsy discovered a sacculated aneurysm, the size of a Tangerine orange, projecting from the lower and posterior part of the arch of the aorta immediately beneath the origin of the left subclavian and common carotid arteries. It had ulcerated into the trachea, without pressing upon it sufficiently to cause much obstruction, the cartilaginous rings being intact.

An Outbreak of Epidemic Catarrhal Jaundice in Derbyshire.—Herbert Peck studied sixty-nine cases of this disease, which he believes to be icterus gravis or epidemic jaundice, sometimes called Weil's disease. It differs from the accounts given of previous outbreaks in its onset, being sometimes gradual, and in the comparatively low temperature recorded, which was usually between 100° and 101.5° F. The incubation period is, perhaps, six or seven days. The period of duration of the disease from exposure to infection to commencing recovery was ten or twelve days, but the jaundice sometimes persisted after complete recovery from the other symptoms. The mode of infection could not be learned from a study of the cases recorded in this outbreak, but bacteriological examination might elucidate it. The disease was not due to the ingestion of food or drink. The popular impression that the outbreak was caused by the drinking of water from a certain reservoir was incorrect, for none but isolated cases occurred outside of two villages, which contain only about 2,000 of the 23,000 persons thus supplied. The disease was probably conveyed by individuals. A post-mortem examination in one case revealed a spleen which was too fragile to allow microscopical specimens being made in gum. The lobular arrangement of the liver was almost lost. The organ consisted of a mass of shaggy connective tissue, a large number of fat cells, and amorpheus *débris*. The kidney showed a marked fatty degeneration of the tubular epithelium of the cortex.

A Case in which, After Erasion of a Tuberculous Elbow, a Thin Gold Plate Was Buried in the Joint for Two Months.—C. B. Keetley reports this case. His patient was a girl of seventeen years. The left elbow was tuberculous, and the writer opened it. He found the synovial membrane and the ends of all three bones diseased, especially the head and neck of the radius and the interior of the olecranon. The head of the radius was excised, and the joint surfaces of the other bones freely removed with sharp spoons. The olecranon remained as an empty shell. The synovial membrane was cut away with scissors. The wound was swabbed with corrosive sublimate and packed with iodoform gauze, iodoform crystals also being inserted. The elbow was fixed at a right angle. One month later, the incisions were opened, disclosing a healthy looking joint, with just a little caseous-looking material in the olecranon. This, together with some granulations, was removed. The joint was washed out with warm bichloride solution. A gold plate was spread over the end of the humerus. The remains of the olecranon were sutured to the ulna with silkworm gut. After the wound was closed the elbow was put up in plaster-of-Paris at nearly a right angle. After eight weeks the plate was removed, and the wound reclosed. Within less than two weeks there was a great deal of smooth and painless mobility in the joint. Four years later a small sinus was found which did not, however, open into the joint. It was scraped out. The movements of the joint are now smooth and painless, and are limited only in the direction of extension.

Berliner klinische Wochenschrift, November 25, 1901.

Early Diagnosis of Arthritis Deformans of the Hip.—J. A. Becher calls attention to two valuable signs for the early diagnosis of this condition. (1) Limited abduction of the thigh of the affected side; (2) The pain in the diseased joint is diminished by exercise and increased by rest. He reports a case in which these symptoms were observed, and sufficed to establish the diagnosis between arthritis deformans and ischiatica.

Reflex Variations of the Pupil in Inflammation of the Optic Nerve.—J. Hirschberg draws attention to certain pupil reflexes which are observed in inflammation of the optic nerve, and which may be utilized for diagnostic purposes. Under normal conditions, if the light is excluded from one eye, the pupil of the other eye slightly dilates. In pupils of average size (3 to 4 mm.) this physiological dilatation amounts to about 1 mm. If, however, inflammation of the optic nerve exists, the dilatation of the pupil of the affected eye amounts to about 8 mm. under the conditions above described. In all cases of loss of vision this so-called pathological reflex dilatation is diagnostic of inflammation of the optic nerve. The author reports a case of hysteria in which blindness came on in one eye. The diagnosis lay between hysterical blindness and an inflammatory optic-nerve lesion. The pathological reflex dilatation present established the latter diagnosis. Subsequent events proved this to be correct. The importance of the value of this sign is to be the more urged because

it is always present early in the disease before the characteristic retinal changes have been established. Furthermore, it is of prognostic worth. During the course of the disease a diminution in the intensity of this pathological dilatation is invariably followed by a subsidence of the inflammation, and ere long, in the majority of cases, a complete return of the normal vision.

Relation of Bovine to Human Tuberculosis.—Prof. Biedert and E. Biedert present a series of new observations which they think confirm the view recently expressed by Robert Koch that bovine tuberculosis is not transferable to man. They cite the condition in a region of Bavaria where the milk industry has long been very extensive, and large amounts are daily consumed by all classes. Sixty to seventy years ago tuberculosis was very prevalent there. With the adoption of preventative measures against the spread of bovine tuberculosis there was a marked decrease in human tuberculosis. Recently, however, although the same preventative measures are in operation, human tuberculosis is markedly on the increase. Investigation shows that during the first period when tuberculosis was extremely prevalent among the people, the manufacture of nails was carried on in the community. With the cessation of this industry human tuberculosis began to decrease. The recent outbreak of tuberculosis is coincident with the establishment of spinning-mills in this locality. Furthermore, those classes which are engaged in the factories show the largest number of tuberculous individuals, while the disease is comparatively rare among those who come into direct contract with the cows, and who drink large quantities of milk. The authors therefore ascribe the prevalence of tuberculosis during the periods mentioned not to the milk consumed by these people, but to an increased susceptibility to this disease brought about by the exigencies of factory life. Additional observation has shown that those regions which show the greatest amount of bovine tuberculosis give a less mortality from human tuberculosis than those localities where bovine tuberculosis is comparatively rare. It was always found that the presence of a large number of cows in a given locality was accompanied by a comparatively small mortality from human tuberculosis. This held true whether or not bovine tuberculosis was prevalent in such a place.

Deutsche medicinische Wochenschrift, November 28, 1901.

Bacteriolytic Substances in Normal Goat-Serum.—R. Pfeiffer and E. Friedberger report a series of experiments which demonstrate the specificity of the bacteriolytic substances present in normal goat-serum. Their work is confined to the study along this line of the cholera and cholera-like vibrios, and of the bacillus typhosus. As is well known, these organisms when respectively placed in a given amount in normal goat-serum are broken down and perish. Such mixtures are, of course, incapable of producing infection when inoculated intraperitoneally into guinea pigs. If now to a given amount of serum a sufficient number of cholera organisms are added, so that all the bacteriolytic substances present in the serum are used up, the further addition of cholera vibrios is without effect upon these, and the mixture upon intraperitoneal inoculation promptly produces infection. If, however, instead of the further addition of cholera organisms, as mentioned above, typhoid bacilli are added, these are straightway destroyed. This proves that normal goat-serum possesses specific bacteriolytic substances, each of which is effective only against one of these organisms. By work similar to the above, the presence of specific substances, operative against the vibrio Finkler, vibrio phosphorescens, and a number of other organisms, has been proven.

Practical Application of the Agglutination Reaction of the Bacillus Tuberculosis.—Robert Koch says that the agglutination-reaction is of very little value in the diagnosis of tuberculosis, and is not to be compared to the tuberculin reaction for this purpose. He examined the agglutinating power of the sera of thirty non-tuberculous and seventy-eight tuberculous persons. In the former a positive result was obtained in 5 with a 1 to 25 dilution, 6 with a 1 to 10 dilution and 1 with a 1 to 50 dilution. Among these were cases of carcinoma, typhoid fever, erysipelas, furunculosis, and muscular rheumatism. Of the tuberculous cases, 1 showed a positive reaction with a 1 to 50 dilution, 4 with a 1 to 25 dilution, and 14 with a 1 to 10 dilution. Contrary to the results obtained in typhoid agglutination, in tuberculosis the further advanced the case the less pronounced is the reaction and the more often it is entirely negative. This fact lends strength to the argument that agglutination is closely related to immunity; for in typhoid fever, as a rule, the more advanced the disease the more pronounced is the immunity; in tuberculosis, however, the reverse is the case. It appears, therefore, that so far as tuberculosis is concerned, the intensity of the agglutination-reaction is a measure of the immunity present. Animal experimentation shows that this is the case. In animals which are being artificially immunized with gradually increased doses of tuberculin, the intensity of the agglutination progressively increases until very high agglutinative values are reached. If, however, at any time the tuberculin inoculations are discontinued or decreased in amount, the agglutinative value of the serum is immediately diminished. Individuals sick with tuberculosis and subjected to tuberculin inoculation give identical results. Furthermore, with the increased agglutinating power, the symptoms of the disease diminish, and in some cases entirely disappear. Observations of seventy-four tuberculous persons have shown that those in the first and second stages of the disease are most suitable for this treatment, and when subjected to these inoculations give the highest agglutinative values. In those in whom the disease is far advanced the increase in the agglutinative power, by this treatment, is slight and soon is entirely lost. Those patients with pulmonary tuberculosis which possess so-called "healed areas" in their lungs are very suitable for this immunization treatment.

Münchener medicinische Wochenschrift, November 26, 1901.

Effect of Ovarian Preparations when Administered After Double Ovariotomy.—A. Flockemann discusses the effect of ovarian preparations upon the climacteric symptoms which frequently follow double ovariotomy. He reports the study along this line of twenty-eight cases. In six the climacteric symptoms entirely disappeared as the result of the administration of these preparations. In four the symptoms were markedly benefited. In nine the condition was slightly ameliorated. In nine no favorable result was obtained. The usual method pursued was to give one or two tablets three times daily for periods of one or two weeks. These results show that the administration of ovarian preparations in this condition is followed by uncertain results, but that in the majority of cases some benefit is obtained, a conclusion which warrants their exhibition in all such cases. They never produce unfavorable symptoms. It is recommended that at the operation a small portion of the ovarian tissue should be allowed to remain, if possible. By this means disagreeable climacteric symptoms may be avoided.

Tetanus Following the Subcutaneous Injection of Gelatin.—F. Kuhn emphasizes the dangers from infection consequent upon subcutaneous injections of gelatin. As is well known, this treatment has found adherents in some quarters in the management of uncontrollable hemorrhage. He reports a case in which the injection was followed by fatal tetanus. The patient, a child, had been operated on for adenoids. It was not possible to control the hemorrhage, although all ordinary means were employed. Accordingly, an injection of 50 gr. of 2-per-cent. gelatin was made into the inner side of the left thigh. Shortly following the injection, the contiguous tissues took on a gangrenous appearance. This increased in intensity until on the fourth day following the injection, a large area of tissue surrounding the site of injection was in an advanced gangrenous condition. The next day tetanic symptoms appeared, which rapidly increased in severity. Death shortly supervened. Bacteriological research gave the following result: Two rabbits inoculated with the heart's blood remained normal, as did also two inoculated with fluid from the gangrenous tissues. One rabbit inoculated with a large piece of the gangrenous tissue promptly developed tetanus and succumbed. One rabbit, which received only a small portion of such tissue, developed slight tetanic symptoms and eventually recovered. The author believes that when gelatin injections are resorted to, great care should be exercised in the selection of the gelatin employed.

Blood Poisoning and Amputation.—Heinrich Wolff warmly urges the advisability of amputation in blood poisoning, when certain contingencies arise, as follows: (1) When, notwithstanding ample drainage, the acuteness of the process continues, new tissues being successively involved, and marked systemic symptoms have developed. (2) When the local process remains stationary, but the systemic symptoms are not alleviated, and the life of the patient is threatened by toxæmia or bacteræmia, in spite of the fact that ample antisepsis is employed at the local lesion. (3) When the primary injury of the affected part is extensive, rendering its complete regeneration and subsequent usefulness extremely questionable. Under these conditions amputation is not only logical treatment, but is generally absolutely demanded to save life. Recent bacteriological researches which have demonstrated the rapid absorption (in a few minutes or hours) of the infective agents into the general circulation have led some to suppose that

amputation under these conditions is useless, since in spite of this operation a sufficient number of bacteria are thus absorbed to produce death. Such is not usually the case, and in the absence of any specific agent effective against the bacterial infection, amputation is the only logical treatment to pursue. The author reports a number of cases to show that even after general infection has taken place and the presence of the causative microorganisms in the blood has been demonstrated, amputation is of avail and may save life. In acute infectious osteomyelitis, amputation is indicated and is often followed by favorable results. A case is reported to emphasize this statement.

Cancer and Malaria.—Professor Kruse advances strong arguments in opposition to Loffler's view that malarial infection is antagonistic to the development of cancer. The latter advocates the inoculation of the malarial parasite as a routine measure in the treatment of cancer. A consideration of the cancer and malaria statistics in different countries and in different regions of the same country disproves this view. Thus in Italy, where malaria is very prevalent, cancer is more common than in Prussia, where malaria is unknown. The same comparison holds true in other malarial and non-malarial countries. If we compare the statistics of the various provinces in Italy, we find that in many instances a high malaria mortality corresponds with a low cancer mortality. This would, perhaps, tend at first sight to confirm Loffler's view. On closer examination, however, we find that this relation does not always hold true, and when we consider the country as a whole, we find that no definite relation exists between the prevalence of malaria and cancer. It has been thought by some that the occurrence of cancer in various localities stands in direct relation to the longevity of the inhabitants. A study along this line of various localities in Europe shows that the variations in longevity are not sufficient to account for the frequency or rarity of cancerous diseases. To a certain degree the condensation of the population is favorable to the development of cancer. As a rule in various countries, those provinces which contain the largest number of densely crowded cities show the greatest cancer mortality. By far the most potent factors in the occurrence of cancerous diseases are climatic conditions. Those countries or localities where such conditions are favorable to the development of corpulency and marked cutaneous pigmentation show, as a rule, the greatest cancer mortality. So far as Italy is concerned, this observation does not invariably hold true when applied to the various provinces. In all probability here the predominating factors are certain racial peculiarities or predispositions. Also in some other countries racial characteristics are of considerable import. The comparative rarity of cancerous diseases in the tropics, for example, is to be ascribed to a natural immunity which the inhabitants of these regions possess.

French Journals.

Cancer of the Liver of the Hæmatoid Type.—Célos reports a cancer of the liver, secondary to a small gastric neoplasm. The hepatic tumor was very large. All of the organ seemed destroyed. The cancer was composed of blood to such an extent that on section most of its substance seemed to consist of this fluid.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, December 5, 1901.

Therapeutic Action of Strychnine.—Fernet insists upon the therapeutic administration of strychnine in alcoholism, tuberculosis, and the adynamic infectious diseases. In the treatment of delirium tremens, opium, chloral, and sulfonal are not equal to this remedy; the rational treatment consists in isolation, feeding, and the administration of strychnine. In tuberculosis, in the adynamic forms of pneumonia, of grip, and of typhoid fever, strychnine also gives good results. It may be administered either by the mouth or by subcutaneous injection.—*La Presse Médicale*, December 4, 1901.

Operative Treatment of Lupus, Extirpation of the Lesions and Autoplasty.—The operative treatment of lupus is not ordinarily practised, and it is only exceptionally employed by dermatologists, for it demands on the part of the operator a certain dexterity united with great patience; and on the part of the patient, too, it is not considered with favor. It is, nevertheless, the best treatment for circumscribed lupus that has not spread extensively, and that is accessible. It gives a rapid cure, and a more satisfactory result from the æsthetic standpoint than the other procedures which are more in vogue.—*Revue de Chirurgie*, November 10, 1901.

Scientific Treatment of Deafness.—Marage describes this treatment as based on two principles: (1) The acuteness of hearing is measured by causing the patient to listen at a constant distance to the sounds of a siren which reproduces the fundamental vibrations of the vowels. The intensity of the sound being proportional to the pressure of the air, the acuteness of hearing is $\frac{1}{n}$ when the pressure of the air ought to be n mm. in order that the sound may be heard. The normal acuteness of hearing $\frac{1}{1}$ is that of an ear which hears a sound under the pressure of 1 mm. (2) The vibrations of the same siren are transmitted to the ear by means of a tube lined with a membrane which transmits all the vibrations without introducing or suppressing any harmonic; massage is given in this way with the vibrations that the ear is fitted normally to receive. According to the writer's observations, this message does not give rise to any buzzing, nor does it ever cause pain. Under its influence, the tinnitus, due to a lesion of the middle ear, rapidly diminishes, and often completely disappears. It seems that sclerous otitis is hindered in its development by this method of treatment.—*La Presse Médicale*, November 27, 1901.

American Journal of the Medical Sciences, December, 1901.

Mastitis Complicating Typhoid Fever.—Fellowes Davis, H. S. Patterson, and A. W. Hewlett report a case of this nature in a woman thirty-four years old. Both breasts were affected. The left breast was opened and about 150 c.c. of thick pus obtained. The temperature which had been septic now fell to normal. Cover-slips and cultures were made and the result showed typhoid bacilli in the abscess in pure culture. A culture tested with the blood-serum of a typhoid patient, and in a dilution of 1:10, gave a well-marked Widal reaction in ten minutes.

Report of a Case of Lymphocytosis, Without Glandular Enlargement.—William Charles White believes the following conclusions to be justified from a study of the case which he reports: (1) That a lymphocytosis may result, when there is absence of enlarged lymph glands, from increased lymphoid tissue in the intestine. (2) That the presence of these cells in the blood-stream is probably due to mechanical causes (Ehrlich). (3) That the lymphocytes in the blood-stream play no part in ordinary inflammatory conditions.

On the Nature of the Disease Known as Erythema Induratum Scrofulosorum.—Arthur Whitfield concludes that there are at least two forms of disease to which the name of Bazin's disease has been given. One of these diseases is essentially indolent, chiefly affects adolescent girls, and is in some cases undoubtedly caused by the living tubercle bacillus. The other affects women of middle age chiefly if not entirely—usually those who suffer from some form of cardiac weakness—is more acute, more amenable to treatment by rest in bed, and has nothing to do with the tuberculous process.

Penetrating Gunshot Wounds of the Abdomen.—Robert G. LeConte gives the following directions for the management of these cases: (1) Remove the patient at once to the nearest place where a clean operation may be undertaken. (2) Assure yourself positively that penetration has taken place. (3) Having demonstrated this fact, always open the abdomen and search for injuries, and make this search systematic. (4) Never wait for symptoms to tell you that profuse hemorrhage or intestinal perforation has taken place, for by that time operation will usually be of no avail. (5) Cleanliness and thoroughness must never be sacrificed to speed.

A Fatal Case of Acetanilid Poisoning.—Philip King Brown reports a case in which the patient's life was sustained eight days after having taken sixty grains of acetanilid. There was general hyperæsthesia and not anæsthesia. There were increased reflexes, and the motor and sensory functions were retained practically to the end. The patient retained nothing on the stomach from the first and was fed per rectum. There was frequent vomiting. Arterial pressure was constantly low and the pulse-rate steadily increased until just before death. The respirations were slightly increased until just before the end, when they were thirty a minute. They were always shallow. The temperature per rectum appears to have been elevated by the toxic dose, but it fell gradually to several degrees below normal. There was a progressive destruction of red blood corpuscles. There was a marked leucocytosis, and a large number of nucleated cells were present. The alkalinity of the blood was diminished 80 per cent. There was hæmatoporphyrinuria, beginning twenty-four hours after the dose was taken, and complete suppression of urine three days before death. There was acute diffuse nephritis, and hemorrhage from the bowels occurred. There was acute progressive jaundice.

Report of Two Cases of Aortic Aneurysm Treated by Means of Silver Wire and Electricity.—Leonard Freeman and J. N. Hall report two cases, and from a study of them conclude as follows: (1) Considering the inefficiency of medical treatment, and the comparative efficiency of the use of silver wire and electricity, it is probably better to proceed to the latter at once without wast-

are valuable [illegible] upon the former. The [illegible] are all the more desirable when we consider that wiring is not a very great danger as proven, and that it is in the early stage of an aneurysm, when the sac is still firm and the patient is in good condition, that the best prospect of cure exists. (2) Soft, undrawn, annealed silver wire, devoid of spring, that is to say, wire just as it comes from the shop, is preferable to the hard, highly drawn wire alloyed with copper and full of spring. It is hardly necessary to coil the wire previously. (3) It is still an open question as to which is preferable, a large amount of wire or a small amount; but the theoretical advantages are in favor of the former. (4) A strong electric current is preferable to a weak one. (5) The cannula through which the wire is introduced should be inserted just within the sac and no further. (6) There is little if any danger of bursting the aneurysm from increase of pressure due to coagulation in a portion of the sac only.

A Case of Myxœdema, with a Study of the Blood and Urine During Treatment.—Thomas P. Prout reports a case of myxœdema in a woman aged forty-five years, which he treated with thyroid extract. The first blood examination was made before the administration of the thyroid. These examinations were all made between 11 and 12 o'clock in the morning. The first count showed 4,203,000 red cells per cmm. The next one, 3,822,250 red blood cells per cmm. After this the number steadily increased. The first drop is explained by the great increase of the fluid elements in the body due to the renewed activity in the various organs of the body. The white blood cells at the various counts were 7,[illegible]; 5,400; 5,400; 6,250; 7,200. The differential count showed nothing distinctive, except perhaps the primary drop in the number of eosin philes, and after that their gradual increase in number. The blood platelets were of large size. They became normal in number but three weeks after the beginning of the thyroid treatment. The hemoglobin value decreased at first, and the red blood cells were of pale color and shape. At the last count the cells were nearly normal. The albuminuria, which was well marked at first, disappeared completely after a time. The largest dose of thyroid taken while the patient was in bed was nine grains daily. She is now taking regularly ten grains daily. Her general condition is excellent at the present time.

Journal of Med. and Science, December, 1901.

Report of Successes in the Treatment of Floating Kidney by a New Method.—J. Ross Watt bases his method of treatment on supporting the entire abdomen. This he does by means of two wing-shaped pieces of sheet-lead, such as used by plumbers, 10 pounds to the square foot, so as nearly to meet in the middle line under good, long-fitting corsets. The straight front is the best, so as to cover all the muscular area bounded by the various bony curves and depressions. Directions are given for making and adjusting the support. The author reports eighteen cases successfully treated. The patients were able to be up and about, to get out of doors and to exercise while wearing the support; their symptoms, consisting of gastric disturbance, dragging pains, headaches, etc., disappeared, and they had increased weight, firmness of muscle, especially of the abdomen, and in a few months or a year were able to give up the support entirely.

Fever in Lymphadenoma.—H. Batty Shaw reports [illegible] of terminal recurrent fever in lymphadenoma or sarcomatous disease. The author says that a consideration of these cases impresses the view that lymphadenoma with recurrent fever is not a special form of disease; that such cases are due to a terminal infection occurring any time during the last year of life of some patients affected with lymphadenoma; that the nature of the bacterial invasion is different in different cases, and that in some cases proof of a bacterial invasion is wanting; that in a considerable number of cases of lymphadenoma with recurrent fever there is great constitutional disturbance with elevation of temperature, rigors, vomiting, diarrhœa, anorexia, and malaise; that in some cases urobilinuria is a marked symptom; that in some of the cases the superficial lymphatic glands, and even the spleen, become very tender and enlarged during the attacks, and that the skin over the enlarged glands may become reddened and show increase of local temperature. The prognosis is, as a rule, hopeless, and the duration of life, after the onset of the periodic attacks of fever, averages about seven and a half months, but it may be as much as twelve or fourteen months.

Atony of the Uterus as a Cause of External Hemorrhage During Uterogestation.—James Oliver says that as soon as fecundation is effected, the vascular activity of the uterus generally becomes augmented, but at about the sixth week of pregnancy, and in response to the irritative influence of those chorionic villi which are destined to participate in the formation of the placenta, the vessels over a localized area of the mucous lining of the uterus increase rapidly in size, and eventually form sinuses. This increase in size is attained at the expense of the wall of the vessel itself, but in virtue of the vital support which the maternal vessels should receive from the opposing chorionic villi, the thinning process must be arrested before the blood pressure is capable of producing deleterious effects. If from any cause the coaptation between the chorionic villi and the uterine wall becomes impaired, rupture of the maternal vessels may result, and hemorrhage of a more or less severe character ensue. In this way hemorrhage is apt to be induced in consequence of atony of the uterus, and as the atony tends to interfere with the implantation of the chorionic villi at the very outset, hemorrhage from this cause is commonly noted as early as the fifth or sixth week of pregnancy.

The Toxæmic Basis of General Paralysis.—John Macpherson, in reviewing the studies of Bruce and Ford Robertson on this subject, says that the paper of the one is purely clinical, the other purely pathological. The former seeks to establish the fact that the symptoms of general paralysis are caused by a bacterial toxin which is constantly or intermittently poured into the system, presumably from the intestinal canal. The latter in his pathological investigations of twelve cases found gastrointestinal lesions, which he believes to have been the effects of a toxic condition. Both authors conclude that general paralysis depends upon a condition of gastrointestinal autointoxication which results from excessive growth of the microorganisms that normally inhabit the alimentary tract. Macpherson, while he considers it premature to conclude that the symptoms of general paralysis are wholly referable to gastrointestinal autointoxication, says there is every reason to believe that such intoxication plays a most important part in the order and development of its symptoms. Before further progress can be made in this direction, the role of the intestinal flora, especially that of the B. coli communis, in the presence of other specific infections of the organism, must be cleared up.

Revue de Médecine, November 10, 1901.

A Case of Ophthalmoplegic Migraine.—Constant Mathis reports the case of a man in whom there was incomplete paralysis of the muscles of the eye innervated by the third cranial nerve. The periodicity of the affection, the pains located on the right side of the head, a history of migraine in the mother, and the beginning of the affection in childhood suggested the malady described by Charcot as ophthalmoplegic migraine. No syphilitic or rheumatic cause was found for the disease, neither were there symptoms of general paralysis nor of exophthalmic goiter, and the author therefore concluded that it belonged to the type of nervous diseases described as nuclear ophthalmoplegia.

Should Fever Be Treated, and If So, How?—Ernest Jendrassik believes that cold bathing in fevers, by abstracting a certain number of calories which immediately have to be replaced, causes overwork of the system, exaggerated combustion which means a considerable loss of substance, and rapid return of the fever; in many ways it resembles the old-fashioned bleeding. If not too cold, it may be sedative, refreshing, tonic, hygienic, but not antipyretic. The author holds that both antipyrin and phenacetin are of value. Phenacetin is best in high fevers, especially in children but, because of its sometimes suddenly losing its effect, may have to be replaced by antipyrin. One to one and a half grams of phenacetin should be given in one dose. The action will last about six hours, and when the temperature begins to rise again, the dose should be repeated, and thus four doses may have to be given in twenty-four hours. Insufficient doses account largely for the dissatisfaction felt by many practitioners with these medicines.

Tympanic Resonance in Acute Pneumonia.—H. de Brun holds that there are three varieties of tympanic resonance in acute pneumonia: the first or premonitory tympanism is a temporary symptom, found at the onset of the disease and indicating that a layer of healthy tissue lies between the surface and the affected area. The second, or *satellite*, tympanism is of frequent occurrence, is found chiefly at the apex, especially in the subclavicular fossa and the axillary space. It is usually in the near vicinity of a hepatized area, but in rare cases at a certain distance from it. The lung itself is the source of these two varieties of tympanism. The third, or *ples-*

simetric, is merely transmitted by the lung. When there is total hepatization, there are two areas in which this resonance may be heard, one in the subclavicular region, which is of the cracked-pot variety, and arises in the trachea and larger bronchi, and the other at the base of the thorax, of a clear sonorous nature, originating in the hollow organs of the abdomen or in the lung of the opposite side. It is a serious sign when both the upper and lower areas of resonance are present at the same time.

Revue de Chirurgie, September 10, 1901.

Resection of the Gasserian Ganglion.—K. Sapejko holds that when neuralgia occurs in all three branches of this ganglion, the seat of the trouble is intracranial, and if the pain is strictly confined to one-half of the face, the Gasserian ganglion is the part involved. Resection of the ganglion is indicated in this case, as it is in cases of severe peripheral neuralgia in which peripheral resections give no permanent relief. To prevent all possibility of relapse, the extirpation must be complete. To this end, the principal branches of the trigeminal will have to be removed, and the otic and nasal ganglia, or at least their connections with the trigeminal, must be destroyed. When the trigeminal is involved, we must differentiate accurately between neuritis and neuralgia. The author gives the various differential symptoms.

Fracture of a Phalanx by Muscular Action.—Charles Féré reports the case of a man whose work on Mosso's ergograph necessitated the immobilization of the hand and of the fingers, with the exception of the middle finger, which by flexion had to lift a weight of three kilograms a second. The position of the fourth finger caused forced extension of its phalanx, and during the course of a long piece of work a cracking was heard at the articulation of the third and second phalanges. There was neither pain nor abnormality of motion. The pulp of the finger swelled, and the tissues around the matrix of the nail became reddened and tense. The radiograph showed a circular projection above the articulation, and a slight backward bending of the phalanx. Muscular action alone could have caused this deformation, as the finger was protected from all other action, either direct or indirect, at the time of the accident..

Malignant Leiomyoma with Visceral Dissemination.—M. Devic and Louis Gallavardin report a case of malignant leiomyoma in a woman of forty-four years. The tumor was situated in the right iliac fossa, and had been in existence for several years, but during the past year had grown rapidly. Six months after it began to increase in growth, there was distention of the abdomen, ascites, and a large tumor occupying the hypochondrium and flank, and the larger part of the abdominal cavity. The liver was hypertrophied, and its edges were irregular and lumpy. At the autopsy a subcutaneous tumor was found near the glutal region. The kidneys, liver, lungs, pancreas, and thyroid body were also affected. Histological examination showed the tumor to be a malignant leiomyoma. This variety of tumor is generally supposed to be benign, but several malignant cases have been reported, involving the uterus and pelvis, the stomach, and the subcutaneous tissues.

Il Policlinico, September, 1901.

Mixed Typhoid and Malarial Infection.—Rufino Fiocca reports the case of a boy who suffered from both malarial and typhoid infection, as shown by the blood examination for the parasites, and by the agglutinating reaction. From November 25 to December 28 the symptoms present were due to typhoid, as proved by the fact that the Widal reaction was progressive, the malarial parasites were absent, and the temperature curve was typical. On the 4th and 31st of January there were attacks of malarial fever, but from the 10th to the 22d of that month there was a relapse of typhoid. The two diseases showed a decided tendency toward remaining separate, one beginning as the other ended. This independence could not be attributed to the administration of quinine.

A Rare Case of Spontaneous Bilateral Pulsating Exophthalmos.—F. Mariani reports the case of a man in whom pulsating exophthalmos came on suddenly after straining efforts. The left eye was practically blind. At the inner and upper part of the orbit was a fusiform tumor in which could distinctly be felt a pulsation synchronous with the radial pulse. The right eye was affected in the same way, but to a less extent. Treatment consisted in a low diet, chiefly of milk, 2 gm. of ergotin daily, and ice bladders applied to the head. The left carotid artery was compressed at intervals of five minutes. Satisfactory improvement has followed. The left eye is still blind, but the conjunctival œdema has diminished, the ectropion and the pulsation are reduced, and the tumor has almost entirely disappeared. The right eye is also greatly improved, the upper lid being easily raised, the chemosis and ectropion are reduced, the exophthalmos is less marked, and the pulsation is scarcely perceptible.

Therapeutic Monthly, October, 1901.

The Selective Action on the Central Nervous System of Some New Morphine Derivatives.—Albert C. Barnes concludes that: (1) While morphoxylacetic acid and its homologues are relatively non-poisonous bodies, their methyl and ethyl esters represent violent convulsion-producing poisons, which in frogs and mammalia excite picrotoxin-like convulsions. (2) While in the frog the spinal cord is associated with the toxic action of the substances, in the case of the rabbit the spinal cord, medulla, cerebrum, and cerebellum remain unaffected. The only point of selective action, giving rise to the characteristic manifestations, is situated in the brain-stem.

A Few Notes on the Salts of Sulphocarbolic Acid.—Edgar Moore Green believes sulphocarbolic acid to be a valuable remedy in cases of nervous irritability of the gastrointestinal mucous membrane, especially when there is much fermentation. The sodium, ammonium, and potassium salts of this acid correct the extreme acidity which is common in these cases, and may be given in 5 to 10 grain doses at intervals of two or three hours. After meals and at bedtime are excellent times to give the medicines. The sodium salt is advantageously combined with the aromatic fluid extract of cascara sagrada. A useful combination is that of acetanilid and sodium sulphocarbolate. This is used for headache and neuralgia. Sodium or ammonium sulphocarbolate in pill form (enteric coated) reaches the intestine and corrects fermentation there. Sulphocarbolate of zinc is useful in dysentery and diarrhœa.

Hysterical Pain and Static Electricity.—Mary Putnam Jacobi believes that hysterical pains imply a partial benumbing of cerebral centers—hysterical anæsthesia and complete loss of function, *i. e.* a paralysis. A local pain which is not increased by pressure can almost surely be referred to the brain. It is the so-called imaginary or subjective pain which so often simulates organic disease, especially utero-ovarian trouble. Electricity should be *the* remedy for hysterical brain exhaustion. The effect of falls, blows, and the like, in causing hysteria, is very marked. The writer, in her treatment of hysterical pain, uses a coil of fine wire, No. 34, with a length of 4,500 feet. She has obtained positive results in the relief of pain in a considerable number of cases. The most marked anodyne effects have been noted in the pains of pelvic neuralgias, unassociated with gross lesion of the uterus or ovaries. The effect of intrauterine treatment in the relief of dysmenorrhœa has also been marked. In superficial pains due to neurasthenia or hysteria in any part of the body, the analgetic effect of the fine-wire, high-tension current will usually yield good results.

Archives of Pediatrics, November, 1901.

Adenoma of Both Adrenals in the New-Born, Associated with Retrogressive Changes in the Adrenals of Marchand.—Alfred Scott Warthin reports a case the most interesting features of which he considers to be: (1) The presence of adenomatous hyperplasia in both adrenals, and probably also in the left adrenal of Marchand, associated with retrograde changes in the right adrenal of Marchand, suggesting a congenital anomaly or defect in the development of the adrenal anlage from the Wolffian body. (2) Suppression of urine and death from uræmia caused by a toxic acute parenchymatous degeneration of the kidneys.

An Unusual Case of Spasmus Nutans.—Samuel Amberg reports the case of an infant of five months, whose head was moving constantly. Rotary movements to both sides were prevalent, but were interrupted by less frequent nodding and shaking movements. The number of the jerky movements was about eighty to the minute. There was blepharospasm which relaxed at intervals; there was no injection of the conjunctivæ, and no oscillation of the pupils. The eyeballs made nystagmic movements of a mixed character. Treatment consisted in the administration of sodium bromide. In less than two months recovery was complete.

Infantile Scurvy and Marasmus.—Francis Huber reports the case of a child, thirteen months old, whose emaciation and general appearance made it absolutely corpse-like. Treatment consisted in the administration of orange-juice whiskey in small amounts, water internally, and salt-solution per rectum; boiled milk and barley water were given hourly in small quantity, gradually increased; later, mutton broth, with rice or barley water, soft-boiled egg, and scraped meat were prescribed, or a piece of steak was given the child to suck. About five weeks after admission the child was practically well weighing thirteen pounds one ounce.

Book Reviews.

TEXTBOOK OF NERVOUS DISEASES. Being a Compendium for the Use of Students and Practitioners of Medicine. By CHARLES L. DANA, A.M., M.D., Professor of Nervous Diseases in Cornell University Medical College, etc. With 240 illustrations. Fifth edition. New York: Wm. Wood & Co., 1901.

THERE is little need in saying much in further praise of a book that has within a relatively few years reached its fifth edition. Doctor Dana's book deserves its success. It is well written, in concise and lucid fashion, containing all that a student need to know concerning nervous diseases, supplying him with facts only, and keeping his mind free from conflicting views and theories. It is, moreover, thoroughly reliable and fully abreast of recent advances.

In the fifth edition, the chapter on myelitis has been entirely rewritten. The author is in accord with other recent writers in believing that "most of the causes produce primarily mechanical destruction, hemorrhages, or thrombosis, and the inflammation is secondary." Speaking of the etiology of acute anterior poliomyelitis, he makes "age, season, and infectious diseases" the three most important factors, and of these, of course, the last-named far outweighs the first two.

The chapter on general paresis has been added in this edition. In this, as in all other chapters, the author condenses within a few pages (7) all the well-ascertained facts regarding the disease, and there is room left for such illuminating and helpful remarks as the following: "An almost sure recipe for producing a case of paresis is this: Let a man of nervous constitution acquire syphilis between the ages of twenty and thirty, then let him work as hard as possible without vacation under great mental strain (worry is still more important, Rev.), drink a great deal of alcohol, and indulge excessively sexually. This will be pretty sure to bring on a case of paresis in ten or fifteen years."

There are slight slips in the make-up of the book. There is no good reason for putting the "Summary of the Hereditary or Family Nervous Diseases" between the various forms of muscular atrophies; but it would be folly to lay stress on such unimportant matter in a book of uniform excellence. For the present, it is the best and most serviceable textbook on neurology in the English language, and as such may well be adopted in every American College.

WARWICK OF THE KNOBS. A Story of Stonington County, Kentucky. By JOHN URI LLOYD, Author of "Stonington on the Pike," "Etidorhpa," "The Right Side of the Car," etc. With photographic illustrations of Knob County. New York: Dodd, Mead & Co., 1901.

THIS is a tale of human interest in which is protrayed a character which we hope, for the good of mankind, is becoming extinct. Warwick was a man of absolute integrity, incapable of compromise, stern, cruel in his obstinacy, utterly devoid of charity, a fatalist in his belief in the predestination ordained by a God as stern, as cruel, and as hateful as himself. The way in which the perverted conscience of this unlovely creature, obstinate beyond belief in his adherence to a cruel creed, brought about the ruin of his entire family is thrillingly told by Mr. Lloyd. The scene is laid in Kentucky during the Civil War, when this State was a recruiting ground for both armies, and the book depicts a phase of American life that should not be lost. It shows the author at his best, and is a worthy companion, both as an entertaining tale and as a local character sketch, to "Stonington on the Pike," by the same writer.

FOODS FOR THE FAT. The Dietetic Cure of Obesity, with Chapters on the Treatment of Gout by Diet. By NATHANIEL EDWARD YORKE-DAVIS, Licentiate of the Royal College of Physicians of London. Twelfth edition, revised and enlarged. New York: Brentano's, 1901.

THIS is a good book on an interesting subject—for even to the most ascetic of us, when hungry, the question of eating is an interesting one—written by a sensible man. The author is not an extremist or a faddist, and one who is, will get little aid or comfort from reading his book. The system advocated by Mr. Yorke-Davis is similar to that of Oertel, but his dietary contains more energy-forming food than does Oertel's; it provides for the rapid decrease of fat, and prevents its reaccumulation afterward, and at the same time restores tone to the heart, muscular and nervous systems, which excessive corpulency much impairs." The book is well worth reading, not only for the many useful directions it contains for the reduction of corpulence and the cure of gout, but also for its hints and suggestions regarding the preservation of health and the prevention of these cognate evils.

"LA TUBERCULOSE EST CURABLE; MOYENS DE LA RECONNAÎTRE ET DE LA GUÉRIR; INSTRUCTIONS PRATIQUES A L'USAGE DES FAMILLES." Par le Dr. ÉLISÉE RIBARD, Membre du Conseil d'Hygiene du XVIe Arrondissement; Attaché au Service des Tuberculeux a l'Hôpital Boucicaut. Avec préface du Dr. MAURICE LETULLE, Professeur agrégé, Médecin en chef à l'hôpital Boucicaut. C. NAUD, Editeur, 3 rue Racine, Paris.

THIS little book, with its encouraging title, is one of the many popular essays written recently as a result of the congress to combat tuberculosis as a disease of the masses, which convened at Berlin two years ago. To educate families concerning the danger from infection of tuberculosis and the means to prevent it, and to give them also an idea how to recognize a tuberculous patient early enough for medical aid to be of value to him, is the object of the little volume before us.

Chapter one is devoted to proofs of the curability of tuberculosis, which in turn are divided in a rather peculiar way, namely, popular, anatomical, physiological, and clinical proofs. Chapter two speaks of infection; chapter three, of the duties of parents; chapters four, five, and six, of the duties of physicians, patients, and the public authorities, respectively. The concluding chapter is devoted to treatment. The only criticism we would wish to offer is that there are too many indications for patients to treat themselves, and in our opinion too many scientific terms have been used for a popular essay. Dr. Ribard's work will nevertheless help much in the anti-tuberculosis crusade now carried on by all civilized nations.

PHOTOGRAPHIC ATLAS OF THE DISEASES OF THE SKIN. By GEORGE HENRY FOX, A.M., M.D., Clinical Professor of Diseases of the Skin, College of Physicians and Surgeons, N. Y., etc. Parts II, III, and IV. Philadelphia and London: J. B. Lippincott Co., 1901.

THIS "Physician's edition" of the author's series of eighty plates comprises over one hundred illustrations, reproduced from almost life-size hand-painted photographs.

There are five pictures in each fasciculus, and most of them are not only fine examples of photographic art, but accurate reproductions in colors approximating closely those seen in life. The plates illustrating pemphigus, lichen planus, psoriasis, lupus vulgaris, and variola are perhaps the most typical and natural.

The text, which is in large type and interspersed with formulæ, reflects the author's beliefs and teachings. It has evidently been prepared with much care and consideration for the needs of the student and practising physician.

There are three illustrations of pityriasis. One labeled pityriasis maculata, the other two pityriasis circinata.

In the descriptive text, opposite the latter, we read "To the circinate form of pityriasis a variety of names have been applied. When it occurs upon the anterior portion of the chest, it is often designated pityriasis rosea, lichen circinatus, or seborrhœa corporis. Upon the extremities and other portions of the trunk it is frequently called eczema seborrhoicum." This statement of the case is apt to mislead.

Circinate seborrhœal lesions, seborrhoic eczema, and pityriasis rosea are now generally considered to be pretty distinct clinical entities, and any attempt to bring them into one class under "pityriasis" would seem to tend toward confusion, rather than simplification. The atlas, when completed, will be a handsome addition to dermatological literature.

A TREATISE ON MEDICAL JURISPRUDENCE. Based on Lectures Delivered at University College, London. By GEORGE VIVIAN POORE, M.D. (Lond.), F.R.C.P., Professor of the Principles and Practice of Medicine, London. With Illustrations. 473 pages and appendices. New York: Longmans, Green, & Co., 1901.

THAT this book is not for experts its preface admits: "The selection of matter and the colloquial style are (*sic*) due to the fact that the chapters were to a large extent originally spoken and not written. The book is intended to place the ordinary practitioner of medicine and law in possession of those facts a knowledge of which is essential."

The style, unfortunately, lacks that precision desirable in scientific treatises. Thus it is said that "toxicology is the science of poisoning" (page 93); that "one or two drops of the tincture of opium seem to have been sufficient to *definitely* kill children" (page 230); and, of atropine, that, as "there is no chemical test for it which is of much value," we should, after ascertaining an alkaloid's presence, thus apply the physiological test: "Put some of the extract into the eye of an animal, and if you get dilatation of the pupil, that is more reliable than anything" (page 282). Nothing is said as to the duration of the dilatation, or of Vitali's or Wormley's tests.

The illustrations are photographs of abnormal mental

types, the author saying that in order to give a general idea of insanity, "apart from those which are dependent upon definite diagnosis of brain disease, the best method was to show you pictures without much comment of my own" (page 417). This comment we would not willingly have lost: "I sometimes tell ladies who nag at their semi-insane husbands, 'You have taken him for better or for worse, and you have put up with him, and if you worry him, he will be worse than he is now'" (page 469).

Some extraordinary propositions of law are advanced, such as this attributed to Mr. Justice Hawkins: "If you, by your wilful act, accelerate the death even of a chronic invalid by a single day, let us say (there is no reason why we should not say a second) by administering that which is likely to do harm, you are guilty of murder" (page 260). If this were law, medical practice would be perilous. The case is mentioned of "a person" who "disappeared in America" and was identified—at least what was left of him, some bones and "a lump of gold"—by an assay showing the gold to be "of identical quality" with that used in "settings" of artificial teeth worn by the missing man (page 208). Apparently, the Webster-Parkman case is referred to; but if Webster had been convicted on no better proof of the *corpus delicti* than such an essay, Boston would have risen in riot. The statement that physicians may be compelled in law courts to reveal professional confidences (page 12) is true in England, but not in the majority of the United States.

The book will give undergraduates and ordinary practitioners a general impression of the subject, and should not be compared, perhaps, with treatises that aim to be authorities, to which, unfortunately, no bibliographical note guides the reader.

As usual in books on this subject, there is no table of law cases. The type and paper are very good, but the binding is for the eye, not the hand.

Infant Feeding in its Relation to Health and Disease. By Louis Fischer, M.D., Visiting Physician to the Willard Parker and Reception Hospitals, New York City. Second Edition. Philadelphia: F. A. Davis Co. 1901. 12mo, 343 pages.

The second edition of this work has undergone much revision and is somewhat enlarged. The notable features of improvement are new chapters on Infant Feeding in Summer Complaint, and an elaborate dietary table for the child after weaning.

The author's treatment of this part of the subject is eminently judicious, and the elaborate and detailed instructions, as to arrangement of diet are calculated to fit the most rebellious cases of indigestion and malnutrition. The author believes in common-sense methods and very properly works on the principle that while science may explain, nature must direct. Nasal and rectal feeding also receive extra attention. The book is practical in every sense and the present edition is well up to the mark.

A Practical Treatise on Diseases of the Skin. By John N. Shoemaker, M.D., LL.D., Professor of Skin and Venereal Diseases in the Medico-Chirurgical College and Hospital of Philadelphia, etc. Fourth edition, revised and enlarged, with chromogravure plates and other illustrations. New York: D. Appleton & Co., 1901.

Those advances which dermatology has shown during the past three years are incorporated in these 892 octavo pages, while especial attention has been paid to improved methods of treatment; new points in symptomatology, pathology, pathogenesis, and diagnosis have, by no means, been neglected, and the author has called for the literature of the entire scientific world for his new material. The number of illustrations in the text is limited, and this is a weak feature of the work.

Advances are not so pronounced in the department of the skin that recent editions should be considered worthless the moment a new one appears.

Students who purchased this work in the original edition may indulge in the present issue if they can afford it; but, with few exceptions, the former will serve as a safe guide for the great majority of cutaneous disorders encountered.

Ready Reference Handbook of Diseases of the Skin. By George Thomas Jackson, M.D. (Col.), Chief of Clinic and Instructor in Dermatology, College of Physicians and Surgeons, New York, etc. With eighty illustrations and three plates. Fourth edition, thoroughly revised. New York and Philadelphia: Lea Brothers & Co., 1901.

This is one of the successful skin books, and each time a new edition is offered, sufficient changes and additions have been made to render it more complete than the last. The new features of this output are sections on acne keratosa, acne urticata, carate, craw-craw, endotheliona, granuloma necrotica, lichen annularis, lichen pilaris, and some others. The size and shape of the volume remain about the same, due to expunging. The author is open to congratulations on the success of this publication.

A Laboratory Course in Bacteriology. For the Use of Medical, Agricultural, and Industrial Students. By Frederic P. Gorham, A.M., Professor of Biology, Brown University; Bacteriologist to the Health Department, Providence, R. I. Philadelphia and London: W. B. Saunders & Co., 1901.

This is a practical book written by a practical man, and will serve as a good manual for students of this interesting science. It is not for medical students alone, but for those interested in industrial and agricultural bacteriology as well, presenting the subject in a general way so as to lay the foundation for later specialization in any branch of bacteriology.

A Manual of Determinative Bacteriology. By Frederick D. Chester, Bacteriologist to the Delaware College Agricultural Experiment Station, and Director of the Laboratory of the State Board of Health of Delaware; Member of the Society of American Bacteriologists, of the Society for the Promotion of Agricultural Science, and of the American Public Health Association. New York: The Macmillan Company, 1901.

This is, so far as we know, the only available work on purely determinative bacteriology in the English language—it is certainly the most complete. The description of each microorganism is given in the fewest possible terms, yet with all necessary detail for easy identification, under the heads of morphology, behavior in different culture media, and habitat. These tables are preceded by brief chapters on the morphology, terminology, and cultural characters of bacteria. The author disclaims that the work is necessarily one on classification, but we are inclined to accord to it an authority in this respect that is equal at least to that of any other in use. But it is preeminently as a laboratory guide in the identification of the various forms of bacteria unknown to the student that the work is to be commended, and as such it is indispensable.

The Century Book for Mothers. A Practical Guide in the Rearing of Healthy Children. By Leroy Milton Yale, M.D., Formerly Lecturer on the Diseases of Children at Bellevue Hospital Medical College, New York, and Gustav Pollak, Editor of *Babyhood*. New York: The Century Co., 1901.

We have in this excellent book an example of a nearly perfect work on popular pediatries. Writers of medical treatises intended for the laity usually err on one side or the other. Either they foster a habit of drug-taking and self-prescribing by giving a list of remedies for every ill, or they fall into the other extreme of indefiniteness and generalization which leaves the inquirer more mystified than he was before opening the book. The authors have proceeded on the theory that the mother "should understand matters of hygiene rather than the treatment of disease; that she should know the things which go to the establishing and preserving of healthful conditions; and that she should be aided in the recognition and avoidance of disease rather than its cure." The first part treats of what the intelligent mother ought to know, and includes chapters on the Preparation for Motherhood, the Nursery, the New Baby, Dress and Clothing, Food and Feeding, Evidences of Illness, Nursery Emergencies, etc. The second part, treating of what the mother would wish to know regarding the care of her child, is made up of a great number of questions concerning the many perplexities of daily nursery life, actual questions addressed to the editors of *Babyhood*, and of the editors' (mostly, we suppose, Dr. Yale's) answers to them. All this information is made available by a copious and well-arranged index. This book can be confidently recommended to every young (or old) mother as a safe and serviceable guide.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S. Edited by T. Pickering Pick, F.R.C.S., and Robert Howden, M.A., M.B., C.M. Revised American from Fifteenth English Edition. Philadelphia and New York: Lea Brothers & Co., 1901. 8vo, pp. 1,256.

The present edition of this popular work has undergone a suitable revision, and some new illustrations have been added. The section of embryology has been somewhat amplified, and a number of new drawings have been incorporated with the text.

SYNOPSIS OF THE REQUIREMENTS FOR THE PRACTICE OF MEDICINE

IN THE VARIOUS STATES, TERRITORIES, AND ADJACENT PROVINCES, TOGETHER WITH THE NAMES OF THE SECRETARIES.

An inquiry was sent several weeks ago to a medical officer in each State and Territory, and also in each of the provinces of Canada, as to the medical regulations in their respective localities, and sincere thanks are tendered them for their prompt replies. Only one State did not respond, and in that case it is probable that either the inquiry or the answer was lost in transit.

An effort was also made to collect some information on the subject of reciprocity of licensure, a subject which resembles the ghost that will not down.

So long as the members of the bar have such freedom of movement in the practice of their profession, it is not probable that members of the medical profession will care to have themselves anchored to any one locality. Neither will they, in middle life, care to become schoolboys again, and be subjected to a quiz-master, to be interrogated as to the paths by which they climbed perhaps to an eminence which makes their services in demand.

It is notable what great progress has been made in the last few years in elevating the medical standard. Not a single State or Territory is now without a medical law, and, with one exception, very stringent ones. It is also to be noted that New Hampshire, which a few years ago had no medical law on its statute books, now has one of the most stringent laws of any State in the Union. Perhaps Arkansas will profit by its example. The more stringent the laws are made, however, the greater should be the care exercised that they be confined in their operation to curing the ills for which they were intended, that is, to protect the people from incompetent practitioners. If that is the object of a medical practice law, let it be confined to that object, and let the incidental inconveniences be removed whenever possible.

Alabama.—Examination before the State Board of Examiners, or before one of the county boards. The latter can examine only the graduates of medical colleges indorsed by the State Medical Association. No provision in the law for reciprocity of licensure with other States. W. H. SANDERS, Montgomery.

Arizona.—Examination before the Territorial Examining Board, and graduation from a lawfully organized medical college. No provision for reciprocity of licensure. Dr. WILLIAM L. WOODRUFF, *Sec.*, Phœnix.

Arkansas.—The applicant must present a medical diploma for registration, or pass an examination before the county board where he resides. No provision for reciprocity of licensure. Dr. R. B. CHRISTIAN, *Sec.*, Little Rock.

California.—Examination before the State Medical Board, and the candidate must have graduated from a medical college, the requirements of which equal those prescribed by the Association of American Medical Colleges. Reciprocity is provided for by law with the District of Columbia or any State or Territory, provided the legal requirements in such State or Territory are equal to those of California, and provided such State or Territory will recognize the certificate of California. No arrangements have yet been made under this provision with other States or Territories. Dr. C. C. WADSWORTH, *Sec.*, San Francisco.

Colorado.—Diploma of a recognized medical college or an examination is required. Only residents of Colorado are registered. Dr. S. D. VAN METER, *Sec.*, 1725 Tremont St., Denver.

Connecticut.—Examination and recognized diploma. No reciprocity provision. Dr. C. A. LINDSLEY, New Haven.

Delaware.—Examination and a medical diploma and a competent common school education. Reciprocity of licensure has been established with some States. Dr. P. W. TOMLINSON, *Sec.*, Wilmington.

District of Columbia.—Examination and medical diploma after study of medicine three years, if granted prior to June 30, 1898, or four years if after that date. Reciprocity of licensure provided for by law, but not yet carried into effect. Dr. WM. C. WOODWARD, Washington.

Florida.—Examination and diploma of recognized medical college. No reciprocity with other States. Dr. M. MCCREARY, Pensacola.

Georgia.—Examination and diploma of recognized medical college. No reciprocity with other States. Dr. J. B. S. HOLMES, Atlanta.

Idaho.—Examination and diploma of a reputable medical college. No reciprocity provisions. Dr. R. L. NOURSE, Hailey.

Illinois.—Examination and diploma of a recognized medical college. The law permits the granting of licenses to graduates of Illinois medical colleges, without examination, but the board requires all to pass the examination. The board will accept the license of other States under certain conditions. Dr. J. A. EGAN, Springfield.

Indiana.—Examination and diploma of a reputable medical college. Any one who matriculated in a recognized medical college in Indiana prior to January 1, 1901, and who with a diploma from such school makes application for a license prior to January 1, 1905, shall be granted a certificate without examination. The law provides for reciprocity, but arrangements have not yet been made for it. Dr. W. F. CURRYER, *Sec.*, Indianapolis.

Iowa.—Examination and graduation from a recognized medical college requiring four years of not less than twenty-six weeks each. No provision for reciprocity. Dr. J. F. KENNEDY, *Sec.*, Des Moines.

Kansas.—(1) Examination after study of medicine three terms of six months each, or after April 1, 1902, four terms of not less than six months each; or (2) A certificate may be granted by the board in its discretion to a graduate of a recognized medical college; or (3) The board may accept the license granted in any State or Territory, or foreign country, having a standard equal to that of Kansas. Dr. HENRY W. ROBY, *Sec.*, Topeka.

Kentucky.—Diploma from a reputable medical college of Kentucky, or from some reputable medical college of some other State or country and indorsed as such by the Medical Board of Kentucky. The secretary says the board has the right to examine applicants from schools not indorsed as reputable by the board. Dr. J. N. MCCORMACK, *Sec.*, Bowling Green.

Louisiana.—Examination and diploma of a recognized medical college, and a fair elementary education. No provision for reciprocity. Dr. F. A. LARUE, *Sec.*, 624 Gravier St., New Orleans.

Maine.—Examination and graduation from a recognized medical college. The law provides for reciprocity with other States having equal standards. Dr. A. K. P. MESERVE, Portland.

Maryland.—(1) Examination and (2) Diploma from an approved medical college, with four courses of study, and (3) Competent common school education. No provision for reciprocity. Dr. J. M. P. SCOTT, *Sec.*, Hagerstown.

Massachusetts.—Examination. The law does not provide for reciprocity of licensure with other States. Dr. EDWIN B. HARVEY, *Sec.*, State House, Boston.

Michigan.—Diploma of a recognized medical college, or examination. No provision by law for reciprocity. Dr. B. D. HARRISON, Sault Ste. Marie.

Minnesota.—Examination, and if graduated after January 1, 1800, must have attended four courses of twenty-six weeks each; if graduated in period of July 1, 1887, to January 1, 1800, three courses of twenty-six weeks each; if graduated prior to July 1, 1887, two courses. Non-graduates must establish their period of

attendance by showing their tickets. The law does not provide for reciprocity. Dr C. J. RINGNELL, Minneapolis.

Mississippi.—Examination. The law does not provide for reciprocity of licensure. Dr. J. F. HUNTER, Sec., Jackson.

Missouri.—Examination, and applicant must also furnish evidence of his preliminary qualifications. No provision in the law for reciprocity of licensure. Dr. WM. F. MORROW, Sec., Kansas City.

Montana.—Examination and recognized medical diploma after attending four courses of six months each, if graduated since July 1, 1898. No provision for reciprocity. Dr. WM. C. RIDDLE, Sec., Helena.

Nebraska.—Diploma of a recognized medical college. Dr. GEORGE H. BRASH, Sec., Beatrice.

Nevada.—Diploma of a recognized medical school entitles to a license, but if the school is not recognized by the board, an examination will be required. No provision in the law for reciprocity of licensure. Dr. S. L. LEE, Sec., Carson City.

New Hampshire.—Examination and preliminary education (completed course in high school or equivalent education), and applicant must have studied medicine four years of nine months each, and have attended four courses of six months each in a medical college registered as satisfactory by the board, and must have received a diploma from a registered medical college or have received a certificate or license giving the right to practise in some foreign country. The law allows reciprocity, but not yet arranged. CHANNING FOLSOM, Concord.

New Jersey.—Examination and high-school education and medical diploma after four years' study of medicine and three years in medical college of good standing. Graduates of foreign institutions must, in addition to above, show that they have full right to practise in the country where the diploma was granted. The law provides for reciprocity of licensure. Dr. E. L. B. GODFREY, Sec., Camden.

New Mexico.—Diploma of recognized medical college (the board recognizes colleges requiring a high-school education and four years' attendance). Otherwise, an examination is required. No provision in the law for reciprocity. Dr. W. G. HOPE, Sec., Albuquerque.

New York.—(1) Examination. (2) Diploma from a medical college registered by the Board of Regents, or a diploma or license conferring the right to practise in some foreign country: (3) The preliminary education required by the board; (4) Study of medicine four years of nine months each, including attendance at a registered medical college four years of six months each. The law provides for reciprocity of licensure with other States and Territories having equal standards. JAMES RUSSELL PARSONS, Regents' Office, Albany.

North Carolina.—Examination and recognized medical diploma. A license to practise in another State may be accepted in lieu of a diploma and entitle to an examination. Dr. J. HOWELL WAY, Sec., Waynesville.

North Dakota.—Examination after attending three courses of six months each. The law has no provision for reciprocity of licensure. Dr. H. M. WHEELER, Sec., Grand Forks.

Ohio.—Examination and diploma of recognized medical school and required preliminary education (practically equivalent to a high-school education). The preliminary requirement applies only to matriculates since January 1, 1900. Those who were matriculated in recognized Ohio medical colleges January 1, 1900, may receive certificates under the Act of February 27, 1896. The law makes provision for reciprocity of licensure, but arrangements not completed for it yet. Dr. FRANK WINDERS, Sec., Columbus.

Oklahoma.—Diploma of a recognized medical college, or examination after having practised medicine five years. No provision for reciprocity. Dr. E. E. COWDRICK, Sec., Enid.

Oregon.—Examination. No law for reciprocity of licensure. Dr. BYRON E. MILLER, Sec., Portland.

Pennsylvania.—Examination, and applicant must have a competent common-school education, medical diploma, or a license giving the right to practise in some foreign country. If graduated after July 1, 1894, he must have studied medicine three years, including three regular courses of lectures; if after July 1, 1895, he must have studied medicine four years, including three courses of lectures. The board may require proof of the above by affidavit. A fee of $25 must be paid when application is made. "Upon the making of said payment and proof, the medical council, if satisfied with the same, shall issue to said applicant an order for examination"; and if the examination is satisfactory, a license is granted. There is reciprocity of licensure. JAMES W. LATTA, Harrisburg.

Rhode Island.—Diploma of recognized medical school or examination. The board recognizes only those schools which have four courses of eight months each. No provision in the law for reciprocity. Dr. GARDNER T. SWARTS, Sec., Providence.

South Carolina.—Examination and diploma of a reputable medical school. Graduates of a medical college in South Carolina having a course of four years are exempt from examination. No provision in the law for reciprocity. Dr. S. C. BAKER, Sec., Sumter.

South Dakota.—Diploma of a reputable medical college and four courses of six months each, if not graduated prior to 1896. No provision in the law for reciprocity. Dr. A. H. ROGERS, Sec., Canton.

Tennessee.—Examination except as to matriculates in Tennessee medical colleges who graduate on or after the June 1902. No provision for reciprocity. Dr. T. J. HAFFEL, Sec., Trenton.

Texas.—Examination. The law provides for reciprocity with other States or Territories with equal standards. Dr. M. M. SMITH, Sec., Austin.

Utah.—Examination and diploma of medical college in good standing. No law for reciprocity of licensure. Dr. R. W. FISHER, Sec., Salt Lake City.

Vermont.—Examination and medical diploma. No provision for reciprocity. Dr. C. W. SERGEANT, Sec., Rutland.

Virginia.—Examination and medical diploma. The law permits the examining board to grant certificates without examination to medical graduates who have been licensed by other States. The board requires that an applicant shall be a graduate of a reputable medical school and pass an oral examination.

Washington State.—Examination and graduation from an institution having at least a three years' graded course. The board has not yet adopted rules for reciprocity. Dr. J. P. TURNEY, Sec., Davenport.

West Virginia.—Examination. No provision for reciprocity. Dr. A. R. BARBEE, Point Pleasant.

Wisconsin.—Examination and diploma from a reputable medical college that requires at least four courses of not less than six months each, and after the year 1901 four courses of seven months each, and an elementary education equivalent to that of the junior class of an accredited high school in the State of Wisconsin, but any student matriculated May 6, 1901, in any medical college in the State of Wisconsin which requires attendance on four courses of six months each shall be granted a license without examination on presentation of his diploma. The law provides for reciprocity of licensure, but the board has not yet arranged for it. Dr. H. M. LUDWIG, Sec., Richland Center.

Wyoming.—Diploma of recognized medical school, or if the diploma is not from a satisfactory school, an examination will be required. No provision of law for reciprocity of licensure. Dr. GEORGE P. JOHNSTON, Sec., Cheyenne.

Cuba.—Graduates of foreign institutions must present degrees from legally authorized institutions to the Depart-

ment of Public Instruction, which degree must fully authorize practice in the country where they were issued, and they must then pass a professional examination

Hawaii.—Examination and diploma from a recognized medical college No provision for reciprocity of licensure. Dr. GEORGE P. ANDREWS, Honolulu.

British Columbia.—Examination, diploma from a recognized medical school after studying four years, and payment of a fee of $100. Dr. J. C. FAGAN, Victoria

Manitoba.—All Canadian graduates must pass an examination in the final subjects and pay $75. British licentiates pay the fee, but take no examination. For American graduates the cases are determined on their merits. If their course of study has not been sufficient, they are not admitted to examination; if sufficient, they may have to take both the primary and the final examination, or they may have to take the final alone. Dr. J. S. GRAY, *Registrar*, Winnipeg.

New Brunswick.—The candidate for a license must have the required preliminary education, have been graduated from a recognized medical college after attendance of not less than four years of six months each, and pass a professional examination. Dr. STEWART SKINNER, *Registrar*, St. John, New Brunswick.

Nova Scotia—The requirements are: (1) Certificate of having passed the required preliminary education (or showing an equivalent) before entering upon professional study; (2) Certificate of attendance at a recognized college, during four years of six months each subsequent to the preliminary examination upon the courses of lectures, etc., prescribed in Section 9 of the Medical Act; (3) Evidence of having passed an examination in the subjects of the foregoing curriculum and of having obtained a diploma from a college which requires a four years' course; (4) Payment of the registration fee. If the applicant has not the necessary degree or diploma, he must pass an examination before examiners appointed by the Provincial Medical Board. Dr. A. W. H LINDSAY, *Registrar*, Halifax, Nova Scotia.

Ontario. The candidate (1) Must have the required preliminary education (about equivalent to college entrance requirements); (2) Must have spent five years in professional studies, including four sessions of eight months in an approved college, and a fifth year in clinical work; (3) Must have passed all the examinations prescribed. Dr R. A. PYNE, *Registrar*, Toronto.

Prince Edward Island.—(1) He must have the preliminary attainments required; (2) Must have studied medicine four years in an approved medical college; (3) Must pass a professional examination. All persons duly registered by the General Medical Council of Great Britain shall be admitted to registration upon payment of the regular fee Dr RICHARD JOHNSON, *Registrar*, Charlottetown.

Quebec—Any one may be registered who (1) Possesses the required preliminary education; (2) Who shall have followed during four years regular medical lectures in one of the universities of Quebec; (3) Have passed a satisfactory examination in presence of the assessors of the college or before the board of examiners Also, any one who, having followed a regular and complete course of medical study in any university of England or France, shall have obtained the diploma of Doctor in Medicine from said university. Also any one registered in the General Medical Council of Great Britain. Also any physician from any other province or foreign country who passes the preliminary examination, studies medicine one year in a university of Quebec, and then passes an examination before the board. Dr. J. P. BOULET, *Sec.*, Quebec.

Classification. The States may be classed in five groups, according to the requirements for securing a license to practise. In the first group (I) may be named the States and Territories which require an examination, diploma of a recognized medical college, and a preliminary education.

In the second group (II) are placed those requiring an examination and a recognized diploma.

In the third group (III) are those requiring an examination only

In the fourth group (IV) are those requiring a diploma of a recognized school or an examination.

In the fifth group (V) are those requiring a medical diploma of any incorporated medical school.

Requirements Classified According to States: *I. Diploma of recognized medical college and a preliminary education.*—New Hampshire, New York, New Jersey, Pennsylvania, Delaware, Maryland, Louisiana, Ohio.

II. *Examination and recognized diploma.*—Arizona, California, Connecticut, District of Columbia, Florida, Georgia, Idaho, Illinois, Indiana, Iowa, Maine, Minnesota, Montana, North Carolina, Utah, Vermont, Virginia, Washington, Wisconsin.

III. *Examination only.*—Alabama, Massachusetts, Mississippi, Missouri, North Dakota, Oregon, Tennessee, Texas, West Virginia.

IV. *Diploma of recognized school or examination.*—Colorado, Kansas, Kentucky, Michigan, Nebraska,* Nevada, New Mexico, Oklahoma, Rhode Island, South Carolina, South Dakota,* Wyoming.

V. *Medical diploma of any recognized school.*—Arkansas.

*Requires a recognized diploma only.

Society Reports.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 13, 1901.

EDWARD K. DUNHAM, M.D., PRESIDENT.

Post-Mortem Changes in the Pancreas Simulating Fat Necrosis.—Dr. O. H. SCHULTZE presented a pancreas which had been taken from a male, thirty-eight years of age. The man had been found dead in the toilet. He was very obese, and the cause of death had been found to be a laceration of the omentum. The abdominal cavity was filled with blood. There was an enormous direct inguinal hernia, which was filled with both fluid and clotted blood. At the internal ring, immediately beneath the peritoneal coat, was considerable ecchymosis. Dr. Schultze was of the opinion that the hernia had contained a large amount of reducible omentum, and that in the effort of straining at stool the mass of omentum passing into the sac was torn, and the hemorrhage thus produced. The pancreas in this individual was the seat of a very large amount of fat invasion. The pancreas being fresh, it had occurred to him to place the organ directly in cold storage. It had been stated that after twenty-four or forty-eight hours under such circumstances a grayish color would appear wherever there was fat. The areas of pancreas in the fresh specimen had been pink; after twenty-four hours these areas were of a distinctly grayish-white color. This tissue, when examined under the microscope, exhibited all the appearances of fat necrosis. The differentiation from post-mortem fat necrosis could be easily made by the coincident occurrence of pancreatic digestion of the cells. In addition to the fat necrosis, there was in this specimen cirrhosis of the pancreas.

Extreme Hypertrophy of the Middle Lobe of the Prostate.—Dr SCHULTZE: It had been gained by autopsy from a negro, aged fifty-two years, and was presented on account of the large size of the middle lobe. The lateral lobes were also enlarged, chiefly anterior to the urethra, each measuring 3x4 cm. on section. The transverse measurement of both together was 7 cm.; the antero-posterior, 5 cm. The third lobe is pear-shaped, symmetrical, and extended into the cavity of the bladder. Near its fundus it was 7 cm. in width and 5 cm. in antero-posterior measurement. The summit of its fundus

was 8 cm. above the caput gallinaginis, and 5 cm. above the junction of middle lobe with the base of the bladder. The wall of the bladder was 1 cm in thickness throughout, the trabeculæ markedly hypertrophied. The mucosa over the middle lobe presented a number of papillæ, varying from 1 mm. to 1 cm. in length.

The ureters were markedly dilated, being 15 cm. in diameter. Both kidneys presented markedly dilated pelves and calyces. Their parenchyma was atrophied and fibrous, and in the left kidney was infiltrated with pus in places. Microscopical examination showed marked hyperplasia of the stroma of the prostate.

Adeno-Carcinoma of the Kidney.—Dr. SCHULTZE also presented a kidney which had been removed from a woman twenty-nine years of age. Almost all of the parenchyma had been occupied by a tumor, which presented on section a number of lobules. Here and there, between these lobules some kidney tissue could be seen. Microscopical examination showed the tumor to be of the alveolar type of adeno-carcinoma. This kidney presented practically the same appearance as some cases of carcinoma of the pancreas, namely, an almost insensible change from normal epithelial structure to that of carcinomatous tissue. Here and there, the kidney was infiltrated with polynuclear leucocytes. The specimen also showed fuchsin bodies, varying in size from one-fourth the size of a red blood cell to ten times that size. Some of them presented a small atrophied nucleus, others no nucleus whatever. These bodies were probably the result of a degenerative change in the epithelial cells themselves, since distinct inclusion in epithelial cells could not be made out, and they were found in greater number in the compressed areas of parenchyma between the lobules of the tumor. In volume, the kidney, which maintained to a great extent the normal form, was four times that of a normal kidney.

A Case of Ruptured Abdominal Aneurysm Simulating Hemorrhagic Pancreatitis.—Dr. L. A. CONNER presented, in connection with Dr. Schultze's specimen, a fresh specimen of clinical interest. The case was one of large ruptured abdominal aneurysm simulating clinically and on post-mortem a hemorrhagic pancreatitis. The specimen had been taken from a male Japanese, thirty-eight years of age, a steward on one of the warships in the harbor. According to the history, the man had been in good health, and while on shore-leave had been suddenly seized in the middle of the night with intense abdominal pain. He had been brought to the hospital within an hour or two, and on admission there had been excruciating paroxysmal pain referred to the left hypogastrium. When seen by the speaker, a few hours later, the man was having attacks of intense pain, with periods of remission. There was constant retching, although very little vomiting. The pulse was rapid and feeble and indicated marked shock. The abdomen was distended and tympanitic, moderately tender and very rigid all over the left side. There was good diaphragmatic breathing. The temperature was 99° F., and the pulse 124. The leucocyte count was 21,000, curiously enough. The case had been a puzzling one, and in making the diagnosis he had inclined to hemorrhagic pancreatitis. In the left flank, one could make out indistinctly a mass like a greatly enlarged spleen. His appearance had not been that of a man who was bleeding profusely, but later in the day he had become markedly anæmic, and he had died about fourteen hours after the attack. Although there was no syphilitic history, there was a well-marked scar on the penis. At the autopsy the peritoneum contained only a little blood-stained fluid, but behind the peritoneum, and pushing all the viscera forward, was an enormous mass of blood, chiefly on the left side, extending down to the margin of the pelvis and infiltrating the mesentery, the mesocolon, and the mesentery of the spleen, and entirely surrounding both kidneys. The pancreas lay in the mass. On removing the aorta, an aneurysm was found presenting just above and to the right of the pancreas. The aorta was the seat of extensive atheromatous degeneration, and this degeneration became extreme near the diaphragm.

A Parasite in the Heart of an Elk.—Dr. HARLOW BROOKS presented this specimen. He said this innocent form of infection might be easily mistaken for trichinosis. The specimen had been taken from an elk belonging to the New York Zoological Society. It had been sick for a long time. The specimen had been removed post-mortem and sent to him. Beneath the endocardium, and all through the muscles, were to be seen small white foci resembling closely those of trichinosis. In this specimen they were not calcified, but they are frequently so. Examination showed the presence of the Miescherschen Schlauche. This parasite is a member of the sarcosporidia, and had been found a half-dozen times in the human subject, but not in this country or in England. Its presence in the laryngeal muscles had been reported. The parasite is a falciform body, and is found within the muscle fiber. It proliferates in the muscle fiber. The spore itself is curved and has a double contour. The chromatin is usually arranged in two distinct masses, but the whole parasite will take a sufficiently active chromatic stain. It reacts to the Gram stain. It varies in size from one-third to twice the length of the hay bacillus. Its presence in the tissues gives rise to very little local reaction, differing in this respect greatly from trichinæ. A deposition of lime salts eventually, thus giving rise to granules very closely resembling the masses found in cases of trichinosis. The specimen is much more distinctly seen in fresh than in hardened or stained specimens. A specimen of this parasite was shown under the microscope.

Dr. MILLER was invited to take part in the discussion. He said that the specimen was interesting to veterinarians because it was so widespread among the lower animals. This particular case was interesting from the fact that the disease had proved fatal. German authorities claim that very few sheep are found in the slaughter-houses of Germany without these parasites in the diaphragm, and it is even more common in the swine of that country. It was not always easy to differentiate it from the trichina. As a rule, the muscle fiber up to the parasite itself is free, while in trichinæ back from the poles in each direction there is always a line of demarkation of broken-down muscle. By applying a weak solution of acetic acid, one can, as a rule, bring out a membrane, which is not the case with calcified trichinæ. Experiments on feeding healthy animals with the meat of other animals containing these parasites had given only negative results, and if it were transmissible there should be a vast number of such cases. The muscle is obliterated by pressure, but the parasite does not invade the muscle. The heart of this elk was flabby and very pale.

A Case of Glanders in the Human Subject.—Dr. N. B. POTTER said that he had seen this case while an interne of the Massachusetts General Hospital, upon Dr. F. C. Shattuck's service. The patient was a male, thirty years of age, who had entered the outdoor department with a story of having had pleurisy in the left side for four days. There had been some pain in the abdomen, and he had been feverish and chilly, but had had no distinct chill. There was nothing else of importance in the history except that he was a hostler. Physical examination showed a large, soft spleen, and a few fine moist râles at the end of the inspiration at the base of the left lung, and in the left axilla. The patient had an irregular septic temperature. At first, he was thought to be suffering from a rheumatic pleurisy. After having been in the hospital for about four days, a red spot developed in the bend of the left elbow, but did not go on to suppuration. Other spots formed on the lower extremity, and these sup-

purated. One of these was opened and the pus examined, but no organism found. After he had been in the hospital for three weeks, a culture was made from the median vein, but it proved negative. The blood failed to give any Widal reaction, and the blood examination was negative, except for the presence of a polynuclear leucocytosis, which increased as the disease progressed. The spots of inflammation spread and became more numerous. The man was then transferred to the surgical side, and several abscesses operated upon. Although some of the abscesses appeared small, on incising them it was found that the pus had burrowed very deeply. No bacilli were found, but some of the pus was injected into the peritoneum of a guinea-pig, and the animal promptly developed a characteristic swelling of the testicle. The man died about five weeks after admission. There was a purulent infiltration of the right forearm near the elbow, near the left ankle joint, on the second toe of one foot, together with an osteomyelitis and numerous pustules in other situations, a purulent synovitis of the right knee-joint; glanders of the nasal mucosa and of the epiglottis; also a chronic pachymeningitis together with acute degeneration of the liver and spleen.

A Case of Pernicious Malarial Fever.—Dr. L. T. LEWALD reported this case. The patient was a man, twenty-three years of age, who had entered Bellevue Hospital on October 19 with a history of having been ill for about two weeks with prostration and moderate diarrhœa. On admission, the temperature had been 98.4° F., the pulse 100, and the respirations 27, but the temperature had very soon risen to 104°. The physical examination showed slight enlargement of the liver and distinct enlargement of the spleen. The diagnosis at first had been typhoid fever, but the Widal reaction was negative. The blood had been examined by one of the hospital internes, but the plasmodia had not been detected. Five days later, the blood had been examined at the laboratory and numerous æstivo-autumnal parasites found, about 5 per cent. of the red cells containing the parasites. There were no crescents. The patient had then been put upon large doses of quinine, but had died suddenly within twenty-four hours. The autopsy had revealed extreme congestion of the brain and what appeared to be punctate hemorrhages in the pons and cerebellum. Microscopical examination of these portions of the brain had, however, failed to show any extravasations—only extreme congestion. There was parenchymatous degeneration of the heart muscle and of the liver, and the latter also showed some pigmentation. The kidneys showed a rather acute parenchymatous degeneration, together with a chronic diffuse nephritis. Microscopical examination showed a large number of malarial parasites in the capillaries of the kidney. The spleen was about three and a half times the normal size, and was exceedingly soft and deeply pigmented. The pancreas was congested and somewhat enlarged. The stomach presented a small ulcer on the posterior wall. The intestine showed marked congestion of its mucous membrane. The pia mater of the spinal cord was congested. The retroperitoneal glands were greatly enlarged and softened.

Specimen of Hour-Glass Contraction of the Stomach.—Dr. LEWALD also presented this specimen, which had been taken from a woman, sixty years of age, who had died as a result of thrombosis of the longitudinal and lateral sinuses of the brain, and embolus of the pulmonary artery. The contraction was at the junction of the middle and distal third of the stomach. The contracted portion would just admit the index finger. As there were a number of adhesions between this part of the stomach and surrounding organs, it was probable that this contraction had resulted from an ulcer. Dr. LeWald also exhibited a very similar specimen obtained from the dissecting room.

Dr. JAMES EWING asked if the urine had been examined in the case of malaria especially with reference to parasites.

Dr. LEWALD replied that the hospital records did not state that any pigment had been found in the urine, but he did not think the examination had been made with this object in view.

Intramedullary Degenerations of the Central Nervous System Secondary to Brain Tumor.—Dr. SCHLAPP presented microscopical sections and drawings showing different parts of the nervous system in a case of glioma with cystic degenerations, involving almost the entire right cerebellar hemisphere. The sections were presented in order to show (which they did) the secondary degenerations that take place in the nervous system in cases of brain tumor. These degenerations are not due to injury of the neuron involved directly by the growth, but indirectly by the effect which the growth has upon the whole nervous system.

Transverse sections through different parts of the spinal chord treated by the Marchi method showed that the posterior columns and posterior nerve roots were alone involved. The degeneration was confined almost entirely to fibers within the spinal chord (intramedullary fibers), and the degeneration extended just to a point where the nerve fibers take their exit from the spinal cord. This fact has been pointed out by other authors (Mayer, Pick, Hoch, and others).

Throughout the whole spinal cord, the columns of Burdock were more involved by the degeneration than the columns of Goll. Many degeneration fibers could be traced into the gray matter of the posterior horns, intermediate gray matter, and into the anterior horns of the spinal cord. The degeneration was most marked in the cervical region, less so in lumbar, and least in the dorsal region. It was found in the lemniscus throughout its course, from the nuclei of Goll and Burdock up to the thalamus. In the cranial nerves, here as in the spinal cord, the sensory nerves only were involved with the exception of the oculomotorius. The trigeminus nerve shows very marked degenerations, which only extend to the point of exit of the nerve from the central nervous system. The fasciculus longitudinalis posterior was also very much degenerated. The right cerebellar superior peduncle was almost entirely degenerated. This degeneration is due to the destruction of the dentate body in the right cerebellar hemisphere, which is the trophic center for the right superior cerebellar peduncle. So, in this case manifestly, the degeneration is attributable directly to the destruction of the trophic center of the neuron degenerated by the tumor.

The tract of Marchi and Loewenthal in the spinal cord shows no degeneration, so that this tract has not its origin in the cerebellum, as these authors thought, but very probably has its trophic center in Deiters' nucleus, which was not injured. Dr. Schlapp says these intermedullary degenerations in the posterior columns of the spinal cord and in the intercranial nerves are analogous to the changes in the optic nerve in brain-tumor cases.

The specimens were treated by the Marchi method and counterstained by acid rubin, which stains the nucleated sheath of Schwann a deep red. This combined staining method served to show clearly that the degeneration in the posterior roots of the spinal cord, as well as in the cranial nerves, extended exactly to where the nucleated sheath of Schwann begins to cover the extra medullary nerve fiber. Hence the speaker concludes that the sheath of Schwann acts in some way as a protection to the myelin substance, or myelin substance and neuraxon.

Degenerations very similar to the above are found in Addison's disease, diabetes mellitus, diphtheria, alcoholism, etc. In a crushed cord case (the cord being entirely severed in cervical region, and patient living eleven days after injury), the speaker found degenerations in posterior roots, in lower dorsal, lumbar, and sacral regions.

similar to the degenerations in the tumor case. These degenerations were intermedullary, that is, not extending beyond the point where the sheath of Schwann begins to cover the nerve fibers. They were not descending degenerations, but evidently caused indirectly by the lesion.

A Simple Apparatus for the Anaerobic Cultivation of Bacteria.—Dr. E. K. DUNHAM exhibited this apparatus. The method is based upon the well-known property of an alkaline solution of pyrogallic acid to absorb oxygen. The apparatus which he now employs allows of an anaerobic condition being rapidly established, and its maintenance verified. It consists of a battery-jar in which the cultures are placed on a suitable support. Over them is placed an inverted tin can or a sheet of tin foil, and over this some absorbent gauze and an inverted battery-jar. Water is poured into the outer jar so as to form a water-seal. A mixture of pyrogallic acid and caustic potash is introduced through a bent tube passing under the edge of the inner inverted jar and opening within the apparatus above the gauze, so that the latter is kept moistened by fresh absorbent solution falling upon it drop by drop. The outer end of the tube is connected with rubber tubing to a separatory funnel placed at a higher level than the jars. The solutions of pyrogallic acid (20 per cent.) and caustic potash (30 per cent.) are mixed in this funnel under a layer of paraffin oil, to prevent oxidation of the mixture. At first the gauze is stained dark brown; when absorption is complete, a white spot appears where the absorbent solution falls upon the gauze. The rubber connection, with the separatory funnel, can then be broken, and the absorbent solution in the bent tube acts as a water seal. The oxygen is removed from the jar in about thirty minutes, and an anaerobic condition can be maintained for at least five days. The whiteness of the gauze is the guarantee that oxygen is excluded.

Dr. W. H. PARK presented a modification of this apparatus. The water-seal and the gauze indicator are employed, but instead of the U-tube a rubber cork is passed through a hole in the inverted jar, and through this two glass tubes, tipped with rubber tubing carrying pinch-cocks, are passed. The pyrogallic-acid solution drops directly through one upon the gauze. Dr. Park said that he was accustomed to make use of hydrogen for the purpose of displacing the greater part of the oxygen in the apparatus, and the pyrogallic-acid solution only to remove the final portions of oxygen. The tubes passed through the rubber cock allow this to be done with the Dunham apparatus. The drop of pyrogallic solution adhering to the tube outlet suffices to make an indicator almost as good as the gauze.

Dr. DUNHAM, in response to questions, said that anaerobic bacteria, *e. g.* tetanus bacilli, or the bacillus aerogenes capsulatus, grow perfectly well in the top of a pile of Petri dishes, covered over completely with tin-foil, within the apparatus described. The foil acts as a metal bell, and it appears that the diffusion of gases is sufficient to remove all but, perhaps, the barest possible trace of oxygen.

The Production of Coma in Monkeys from Intravenous Infusions of Beta-Oxybutyric Acid.—Dr. C. A. HERTER made some remarks on this subject. He said that some observers had been inclined to attribute the coma not so much to the acid as to the presence of toxins. Klemperer of Berlin was one of those who takes this view. It was, therefore, interesting to know whether the mere introduction of an acid into the circulation was capable of bringing about anything comparable to the coma found in man. The experiments conducted with the object of testing this point could hardly be made very satisfactorily on other animals than monkeys. He had used 5-per-cent. acid solutions of oxybutyric acid in two experiments on monkeys. The first case had failed through imperfect technique, but the second experiment had been strikingly successful. In the first experiment, after the injection of 30 c.c. of the acid solution, the animal yawned continually and became very drowsy. After the injection of 60 c.c., the animal gave a few short gasps and died. The heart-beat could not be felt during the last few minutes of life. No urine was passed during the infusion. The autopsy was entirely negative. There were 6 c.c. of urine in the bladder, and it gave a distinct reaction with ferric chloride, but ceased to give this after boiling. The urine before the injection had not given this reaction. The urine contained a small quantity of albumin. In the second experiment, after 33 c.c. had been injected, the animal rather suddenly became stuporous, and it became impossible to arouse it by pricking the skin. For two hours and a half the animal lay in a stupor, but two hours later it appeared entirely normal, and by the next day seemed as well as usual. There was complete absence of cyanosis throughout the experiment. Somewhat less than half a gram of oxybutyric acid per gram of weight of the animal was used. These experiments strengthen the view that the coma seen in the human subject is referable to the oxybutyric acid in the blood, yet he was inclined to believe that there were contributing causes, such as infections, in some instances.

Dr. A. MAYER said that he thought Dr. Herter had been the first to make these experiments on monkeys, though similar experiments had been made on other animals, and not with the success achieved by Dr. Herter. The opinion to-day was rather prevalent that diabetic coma is produced by oxybutyric acid principally. It had been claimed that with the sugar burned up in the body, other less oxidizable substances were also consumed, such as B-oxybutyric acid (and its derivatives, diacetic acid and acetone), and that in the healthy subject these substances do not appear in the urine. When, for some reason, as in diabetes, the sugar is not burned up, these substances appear in the urine. It was claimed that this could be produced artificially by withdrawing the carbohydrates from healthy individuals. Apparently, to strengthen this view, Schwarz* had made some observations on the diminution of diacetic acid and acetone in diabetic subjects. These two bodies are the derivatives of the oxybutyric acid. He had given glyconic acid and sugar acid to diabetics, and had marveled at the rapid diminution of the diacetic acid and the acetone in the urine in diabetic subjects. The following year† he had experimented upon a case of diabetic coma under his observation. A large quantity of Beta-oxybutyric acid was found in the urine, and on a certain date, symptoms of coma had developed—dyspnœa, rapid increase of respiration and pulse, along with vomiting. The symptoms had been allowed to progress until coma had developed, and then the patient had been given some glyconic acid—the equivalent of 70 grams, neutralized by bicarbonate of soda. The success of this experiment had been simply marvelous, as the patient in a short time came out of his comatose state and remained so for about three weeks. The patient had then become comatose, and had again improved under the use of the glyconic acid. A third time, two or three weeks later, coma had appeared, but the supply of glyconic acid had been exhausted. The patient died. This experiment of Schwarz would seem to prove that Beta-oxybutyric acid or its derivatives were really the cause of diabetic coma, and that perhaps we had found some substance to prevent its development, or coma having appeared, some substance which would bring the patient out of this state. Dr. Mayer said that he would suggest that glyconic acid should be given to a monkey previous to the infusion of oxybutyric acid, and then note whether

*Leo Schwarz, "Ueber Aceton-Ausscheidung," im Congress für Innere Medicin, 1900.

†*Prager med. Wochenschrift*, Juli und August, 1901.

it is possible to produce coma by such an injection. Dr. Mayer said that he had been the first one in this country to indorse the theory of the bacterial origin of diabetes, although he had not published his writings until 1898. Although the disease may be of bacterial origin, he was inclined to think that the coma itself is the result of the oxybutyric acid in the blood.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, December 5, 1901.

HERMAN KNAPP, M.D., VICE-PRESIDENT, in the Chair.

Portrait of Dr. Edward G. Janeway.—Dr. J. E. JANVRIN said that two years ago he had suggested that a portrait of Dr. Janeway be procured by subscription and presented to the Academy, but Dr. Janeway had met this proposition with the promise that if the subscribers would secure a portrait of the late Dr. Austin Flint, after it had been presented, he would give to the Academy a portrait of himself. In accordance with that promise, the speaker said, he had the pleasure on this occasion of presenting to the Academy the portrait of Dr. Janeway.

Some Surgical Tendencies from a Medical Point of View.—Dr. REGINALD H FITZ of Boston delivered the anniversary discourse, taking the above for his theme. He said that physicians had been duly impressed with the diminution in the mortality rate of surgical operations, but they were deeply concerned with the ultimate results of these operations. Experience had shown that cases formerly considered to be very dangerous, if not fatal, had been relieved, or even cured, by surgical means. The surgeon of the present day was apt to demand that cases be turned over to him at so early a stage that it is impossible for the physician to make the diagnosis, the surgeon assuming that it is better for him to do an exploratory laparotomy and thus make the diagnosis. Sometimes an early operation done for a supposed appendicitis shows no inflammation of the appendix, or an operation undertaken for an intraabdominal growth, shows only a phantom abdominal tumor. Dr. Fitz says that he had had the records of the Massachusetts General Hospital searched from 1890 to 1900 to obtain statistics concerning the results of the surgical operations done there by the several general surgeons connected with that institution. From a study of these statistics it seemed apparent that except in specially selected cases exploratory laparotomy is attended by considerable risk to life and considerable doubt as to the degree of relief attained. Operations sometimes prolong life, but one should consider whether this added life is worth the living The surgeon was apt to raise the hopes of the sufferer too high by the citation of statistics of operations which hardly represent average results. Dr. Fitz said that he had made a special effort to determine the ultimate results of operations done at the Massachusetts General Hospital on diagnosticated and demonstrated cancer of the stomach and intestine. Replies had been received from nearly three-fourths of these cases, and the pathos of some of them was very impressive. There had been twelve operations for cancer of the stomach. In most of these life had been prolonged only a short time, and had been full of suffering. There had been nine cases of intestinal resection, of which eight had died within one month after operation, while one was enjoying good health two years and a half afterward. There had been forty-nine inguinal colostomies, thirty-seven of which had been followed. Less than one-fifth of the cases heard from had been living one year after operation. Of the seventeen Kraske operations for rectal cancer, six had not been heard from; but of the other eleven, seven had died within a year following the operation. One patient had remained in the hospital for two months, had then returned home, and lived four weeks suffering all the time. Of the seventy-seven cases of cancer of the alimentary canal, whose subsequent history had been learned, 21 per cent. had died within one week, 54 per cent. had died within one month, and 73 per cent. within six months after operation. Of fifteen cases of intracranial tumor, the subsequent history had been obtained from only ten. Four had died on the day of the operation, and others a varying number of days thereafter, so that eight out of the ten had died in the month following the operation. The treatment of tumors of the kidney, the speaker said, also occupied debatable ground. There had been eleven nephrectomies for malignant disease of the kidneys, and replies had been received from eight cases. Four had died within a fortnight, one after two months, one at the end of three months, one after five months, while one was living and practically well three years after the operation. In the last case, the growth, which was said to be a sarcoma, originated in the suprarenal capsule. The operative treatment of goiter was now known to be demanded only for such cases of goiter as have undergone secondary changes. We also knew now that the treatment of such cases by iodine, and perhaps also by phosphorus, was successful in all but a very small percentage. While the removal of a portion of a sporadic goiter might effect a cure, it by no means followed that a similar operation in Graves' disease would give a like result—indeed, very disastrous results were apt to follow in this variety of enlarged thyroid. The surgical treatment of malignant lymphoma was another subject of dispute. The very significance of the term "malignant lymphoma" was disputed. The uselessness of extirpation of the tumor in leukæmic lymphoma seemed to be pretty generally recognized; nevertheless, operations for this condition were remarkably frequent.

In conclusion, the speaker said that he had not presented the foregoing facts to oppose the beneficent work of the surgeon, but simply to emphasize the shortcomings of his art, and the need for a careful and conscientious selection of cases. He recognized and appreciated fully the great advances made in recent years in the field of surgery, yet it could not be denied that its blessings to mankind had not always been unalloyed.

Natural Method of Draining the Peritoneal Cavity.—John G. Clark says that in many cases drainage, as ordinarily employed, is superfluous or even dangerous, and the rational method is to remove all possible débris and infectious matter by thorough irrigation, and then leave one liter of salt solution (0.6 per cent.) in the abdominal cavity, and in order to promote and hasten natural drainage, supplement this by an enema of a liter of salt solution, given while the patient is well under anæsthesia, and in the Trendelenburg posture. Under this plan the patient is greatly stimulated, shock is minimized or averted, urinary excretion is increased, toxic matters are more easily eliminated without irritation to kidneys or bladder, peritoneal infection is quickly eliminated, thirst is alleviated, and intestinal peristalsis is promoted—all of these factors combining to reduce mortality after abdominal sections, to decrease the pain, discomforts, and complications of the first forty-eight hours, and to hasten recovery.—*University of Pennsylvania Medical Bulletin.*

The Insurability of People Who Have Lived in Tropical Countries.—C. L. Van Der Burg reaches the following conclusions from his study of the subject: (1) The insurance of people returning from hot countries needs a special examination: (*a*) We must find out how the change of climate has been borne; (*b*) We must look for the symptoms of tropical diseases, such as elephantiasis, leprosy, aneurysm of the aorta, beriberi, chronic dysentery, psilosis, renal and vesical calculi (which are often observed immediately after the return to Europe), and malaria. (2) The insurance companies should intrust the examination of such people to physicians who have lived in the tropics, and preferably to those who are acquainted with the region these applicants inhabited.—*The Medical Examiner and Practitioner.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 14, 1901.

	Cases.	Deaths.
Measles	596	23
Diphtheria and croup	234	43
Scarlet fever	230	11
Smallpox	10	2
Chickenpox	51	..
Tuberculosis	231	141
Typhoid fever	64	10
Cerebrospinal meningitis	..	3

The Fee and the Show.—Recently one of the best-known physicians in New York died, a man with a reputation on two continents, who reached the acme of his fame early and had far more than the average years of extreme prosperity. Yet, when his estate was computed, great surprise was expressed on every hand at finding that he had managed to save during a long and busy life only the earnings of two or three years. The same occurrence can be noted every day. A supposedly prosperous physician dies leaving nothing, while his son gives up his college education and his daughters are compelled to eke out an uncongenial existence as teachers or stenographers.

No doubt, the incomes of most physicians are greatly exaggerated. The average income of the well-established city physicians is probably nearer twenty-five hundred than five thousand dollars, while the general average is said to be far below one thousand. But physicians apparently leave much less behind than other men with similar incomes.

The business training of physicians is to quite an extent responsible for this. Each one does a vast amount of charity work for which he gets little credit, and this is especially true of the men who have an appearance of prosperity from the relative size of the fees they do collect. He is a poor collector, sending out his accounts at infrequent and irregular intervals and creating the not unnatural impression that he does not need the money. Small wonder then that the family medical bill is paid only after all other reasonable family desires have been satisfied.

We do not suppose it is possible to suggest any satisfactory fee scale, but it is self-evident that the scale which taxes the clerk a day's wages for consultation while his employer escapes with the income of a minute is, to say the least, not an equitable one. Neither can the system be defended as businesslike by which the physician treats for nothing a multitude of patients who would willingly pay a small fee for the same service, if the fee were in proportion to their means. And if the fees at one end of the scale are too high, those at the other end are certainly too low, as compared to other professions. The man who does not begrudge his pastor a handsome fee for a ten minutes' wedding ceremony, very often thinks the same fee too much for as many hours' work in facilitating the advent of his first born. The business man pays his attorney a large fee for drawing his will in an emergency, and then disputes the account of the surgeon who obviated the immediate necessity of that will.

This inferior business instinct also shows itself in a false professional pride. The laity generally rank a physician according to the location and beauty of his office and the size of his consultation fee, and very many members of the profession are unable to get rid of the same pernicious idea. As a consequence, the aspirant invests his income in an expensive office, charges an exclusive fee, and fritters away hours in idleness rather than accept the smaller sums which he might have. Such policy is good business for a few, but there are not rich patients enough for all, and if one adopts the plan he should do it with the clear understanding that the chances are distinctly against him. After all, the ones who lead the busiest, happiest professional lives, who do the most good in the world, and who leave the most behind are the ones who have the least of this false professional pride.

While it may be good business policy to have an office in an exclusive neighborhood, by it insuring larger fees and a more exclusive practice, the same reasoning does not often apply to a residence in the same neighborhood unless it be amply within one's means. Of course, the physician likes to have his family live well and enjoy the society of many of the people who are his patients; but when, on an income of five thousand, he tries to live next to and like the banker on a hundred thousand, he pays a ruinous price.

Certain portions of our large cities are crowded with physicians attempting just this thing. They have the superficial appearance of prosperity; their families are apparently perfectly secured against want and live in style only justified by quadruple the income. After the funeral it transpires that the utmost endeavor has paid the rent or kept up the interest, while the family living has been made from the renting of furnished rooms.—*N. Y. State Jour. of Med.*

Origin of Absinthe.—The New York *Herald* says: "Temperance people in Europe were recently much surprised at the discovery that the deadly absinthe was originally an extremely harmless medical remedy. It was a French physician who first used it His name was Ordinaire, and he was living as a refugee at Couvet, in Switzerland, at the close of the eighteenth century. Like many other country doctors at that time, he was also a druggist, and his favorite remedy was a certain elixir of absinthe, of which he alone had the secret. At his death he bequeathed the formula to his housekeeper, Mlle. Grandpierre, and she sold it to the daughters of Lieutenant Henriod. They cultivated in their little garden the herbs necessary for concocting it, and after they had distilled a certain quantity of the liquid they sold it on commission to itinerant pedlers, who quickly disposed of it in the adjacent towns and villages. Finally during the first decade of the nineteenth century, a wealthy distiller purchased the formula, and very soon afterward he placed on the market the modern absinthe, which differs greatly from the old medical remedy, since the latter contained no alcohol and very little absinthe."

Statistics of Negro Illiteracy.—Taking the negro males in the Southern States of voting age, the illiterates are: 61.3 per cent. in Louisiana, 59.5 in Alabama, 56.4 in Georgia, 54.7 in South Carolina, 53.2 in Mississippi, 53.1 in North Carolina, 52.5 in Virginia, 49.5 in Kentucky, 47.6 in Tennessee, 45.1 in Texas, 44.8 in Arkansas, 42.7 in Delaware, 40.5 in Maryland, 39.4 in Florida, 37.8 in West Virginia, and 31.9 in Missouri. In New York, on the other hand, where there are a great many negro men of voting age, the percentage of illiteracy among them is only 11.3, while in Pennsylvania it is 17.5. In Kansas, whither a great many negroes have gone, the percentage among them of adult male illiteracy is 28.1. In the District of Columbia, which has a large negro population in fairly good economic circumstances, the percentage of male illiteracy is 26.1. The negro colony of Massachusetts numbers 40,000 souls, and only about 10 per cent. are unable to read and write.—*Review of Reviews.*

Immigration by Nationalities.—*The National Geographic Magazine* for November has an article on "Immigration and the Census" and in it are noted the nationalities that make up our total immigration, amounting to 19,115,221 in eighty years. Germany has contributed over one-fourth, 5,009,280; Ireland slightly more than one-fifth, 3,869,268; Great Britain one-fifth, 3,026,207;

Norway and Sweden nearly one-fifteenth, 1,240,312, Canada and Newfoundland 1,049,939; Italy, 1,040,457; Austria-Hungary, 1,027,195; and all other countries about one-tenth, 1,919,661. Probably one-fourth of our immigrants have during the past ten years returned to their old homes. Three and one-half millions are recorded as having entered the country, but there is an increase in our foreign-born population of only about one million, conclusive proof that many remain in America for only a short period.

World's Tobacco Users.—According to recent statistics, the average consumption of tobacco by each person in the various countries of the world is as follows: Netherlands, 3,400 grams; United States, 2,110; Belgium, 1,552; Germany, 1,485; Australia, 1,400, Austria and Hungary, 1,330, Norway, 1,333; Denmark, 1,125; Canada, 1,050; Sweden, 940; France, 933 Russia, 910; Portugal, 850; England, 680; Italy, 635; Switzerland, 610, and Spain, 550.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended December 14, 1901:

SMALLPOX—UNITED STATES.

		CASES	DEATHS
California, Los Angeles	Dec. 3,	1	
Illinois, Chicago	Nov. 30-Dec. 7,	1	
Peoria	Nov. 1-30,	41	
Indiana, Evansville	Nov. 23-Dec. 7,	3

The Criminal Negro.—In the *Arena*, November, Miss Frances Keller concludes her series of articles on the above subject. The result of her investigations goes to show that, with reference to climate, soil, food, and economic and social conditions in general, the negro compares to disadvantage with any other class in America, that Southern prisons are rather conducted with a view to profit than to a suppression of crime, that the physical and mental status of the race should not discourage educational efforts, and that the environment in the South is favorable to the commission of crime by negroes.

New Seasickness Remedy.—Professor Heinz of the University of Erlangen claims to have discovered an infallible and very simple antidote against seasickness. "Draw a long and vigorous breath at frequent intervals," he says, "and you will never suffer from this malady." The reason, he explains, is because the initial cause of seasickness is to be found in a lobe of the brain, the sensitiveness of which reacts on the stomach, and that when fresh air is breathed at frequent intervals the blood becomes charged with oxygen and thus the offending lobe loses its sensitiveness.—*New York Herald.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE NEUROTIC INDICATIONS OF PRE-SENILITY.

BY ALLAN McLANE HAMILTON, M.D., F.R.S.E.,
CLINICAL PROFESSOR OF MENTAL DISEASES IN CORNELL UNIVERSITY MEDICAL COLLEGE,
NEW YORK.

THE old saying that "a man is as old as he feels," is only in part true. It is sometimes claimed that "a man is as old as his arteries," which is the pathological and more exact way of putting it. Both these statements are correct, for many of the first warnings of "break-down" are subjective, and are connected with the nervous system, and depend more especially upon easily aroused variations of the cerebral circulation due to an impaired tonicity of the vessels. Such instability, though scarcely beyond the physiological standard, is apt to be followed by warning symptoms which betoken commencing involution of the human apparatus, and are often made light of by the individual himself, or by the physician to whom he may be urged to go.

Our national characteristics are notably such as to invite a premature decline in force and energy through over-use of our nervous systems; but possibly after several generations we may cultivate the same stability which is characteristic of older peoples. While it is almost an affectation to adopt the terms "Americanism," "American neurosis," or "American neurasthenia," as some of our Teutonic critics are disposed to do, I think I may safely say that many of us do break down at an earlier age than our foreign neighbors, and this is largely because our struggle for the rapid accumulation of wealth, for the gratification of an ambition, which is due to competition, and not in a small measure to the stimulation of our newspapers.

Many commence business life in their teens, taking little or no exercise of a beneficial kind and insufficient mental exercise of a recreative order, readily adopting the luxurious life of continental Europe, and in our unrest carrying everything to extremes. A pernicious influence of a part of the press fosters in young people the ambition to "hustle," and to select careers for which they are unfitted. Men who should be behind the plough, or in the counting-house, adopt professions for which they are not adapted, and often break down through attrition or thwarted ambition. The necessity of keeping up a certain appearance implies a constant and fagging use of brain power, which is accompanied by worry, and anxiety of the kind that makes men prematurely old. And what injury such strife does not bring about, is wrought by the stock market.

Our physical health is, on the other hand, impaired by overeating and insufficient exercise, and we ordinarily use too little judgment in the selection and taking of food, so that gastric and intestinal complaints, among which are distention of the stomach, chronic catarrh of the mucous membrane of the stomach and intestines, defective metabolism, and diarrhœa are not infrequent. Various toxic conditions are an accompaniment of this state of affairs, so that the nervous system is supplied with vitiated blood, and arterial disease is invited.

It should be unnecessary in this connection to refer to the familiar dangers of alcohol and tobacco, both of which are usually indulged in in an irrational way, or to the taking of medicines and drugs. There are now many accommodating manufacturers who supply tablets representing attractive formulæ that are within the reach of the amateur physician who has himself for a patient. Perhaps more harm has been done by such indiscriminate taking of the coal-tar preparations, which are easily obtainable, than by any other remedy.

Such standard and conventional tests of senility, as hardened and tortuous vessels, premature baldness, the arcus senilis, and other appearances are usually regarded as danger signals, and indicate the approach of senility; but, after all, these suggest an advanced condition of degeneration, and, when present, it is too late to do much. Even the occasional presence of albumin and casts in the urine is not regarded nowadays as having the importance that it formerly had; but, as a rule, when urinary changes, sufficient to cause these manifestations, exist, a great deal of mischief has been done, and especially is this the case when our patient is a man still under fifty, who has led a "strenuous life" of the kind I have described.*

It is difficult to fix a standard of mental vigor, or to say when true senility should show itself. Clouston says:

"Physiological senility means no reproductive power; greatly lessened affection faculty, diminished power of attention and memory, diminished desire and power to energize mentally and bodily, lowered imagination and enthusiasm; lessened adaptability to change, greater slowness of mental action; slower and less vigorous speech as well as ideation; fewer blood corpuscles, red and white; lessened power of nutrition in all the tissues; a tendency to disease of the arteries; a lessening in bulk of the whole body, but notably of the brain, which alters structurally and chemically in its most essential elements, the cellular action and the nerve currents being slower, and there being more resistance along the conducting fibers. In the young man there is organic craving for action, which, not being gratified, results in organic discomfort. In the old man there is an organic craving for rest, and not to gratify that which causes organic uneasiness."†

These changes, of course, correspond to the normal weakening of age; but, whenever they begin to appear before fifty, there can be little doubt that pre-senility exists, and they become pathological, instead of physiological.

A study of a large number of cases of pre-senility has convinced the writer that there are many symptoms, especially of disturbance of the nervous system,

* *Vide* "On the Advantage of a Trace of Albumin and a Few Tube Casts in the Urine of Certain Men About Fifty Years of Age." Wm. Osler, M.D., LL.D., *Medical Journal*, New York, November 23, 1901, page 949.

† *Vide* "Lectures on Mental Diseases," by T. S. Clouston, M.D., Edin., F.R.C.P.E., etc. American edition: H. C. Lea's Son & Co., 1884, p. 395.

which are not taken into account as often as they should be, and these invariably indicate commencing disturbances due to vascular degeneration. While the study of the pulse and heart in arterio-sclerosis has been quite extensive, the writer does not think that its connection with mental variations and deterioration has been fully described. The pulse has a certain instability in subjects of this kind which can be determined only with difficulty, unless the subject is under daily observation. If sphygmograph tracings are taken *at different times in the day*, a wide variation is presented as the mental equilibrium of the individual is disturbed by changes in blood tension; and it will be found that the elevation of the first line and the character of the tidal-wave line will vary with the hyperæmia of the brain and the associated cardiac muscular instability; or, if the vascular tension has endured for some time, there will be found an appearance presenting the slanting up-stroke, and the long receding stroke, interrupted by numerous indentations, which is so characteristic of general paresis.

That condition of cerebral irritation so well described by Fothergill many years ago, when in an ordinary anæmic brain flushes of hyperæmia occur, is an evidence of pre-senility, as well as earlier ischemic states. The mental impairment attendant upon altered blood pressure and consequent malnutrition of the cortical elements are recognized by the patient himself as well as by others. In ordinary men under good self-control, there is a stability which is quite altered in the pre-senile state. Under slight emotional stimulation they become flushed and irascible, or lose the patience and ability to throw off care which may have been characteristic of former years. Hypochondriasis, too, is a development of that introspection which accompanies a limitation of mental power and easily produced brain fag. Among other early indications of mental failure is the indisposition to make intellectual exertion, and a tendency to avoid anything that may be regarded as complex reasoning. The association of ideas is weakened. He will be indisposed to indulge in contrasts of ideas with the same vigor that he had in previous years. As a rule, he tries to arrive at the result desired with the least effort and in the quickest way, and much of his mental activity is automatic. His weakness is especially shown in following out new channels of thought, or accepting and storing away fresh impressions. We find him, therefore, indisposed for exertion. If he be a professional man, he creates little or no new work, and under all circumstances he seeks the broad road of colloquialism and thoughtless speech; and old mental habits become stronger than ever, and he is relieved when he accomplishes what is required of him. While he is conscious of his failing power, he accepts the failure with resignation; or, on the other hand, chafes at the success of others. An early impairment of memory, especially of substantives, annoys the subject, and this keeps pace with a kind of apathy and dulness. Little mistakes are made in calculations, letters are misdirected, and checks unsigned. These may be insignificant omissions, but they may grow to be evidence of pathological weakness.

Many men between thirty and forty, who have enjoyed good health and have clear brains, are apt, under the stress of hard work, to suffer from headache of a peculiar kind, and these are undoubtedly connected with sudden change in the diameter of the cerebral vessels. In some respects, they resemble the angiospastic orm of migraine—but the pain is sub-occipital or frontal, and usually bilateral. Such attacks nearly always follow fatigue, and occur after a particularly trying day in court, a night without rest, or the execution of a laborious literary task. There is pallor, small pulse, subjective coldness, loss of appetite, emotional depression, and the copious discharge of large quantities of limpid urine of clear color and low specific gravity. There is reactionary dulness and fatigue, and a disinclination to repeat the work. During the attack, hemiopia is an occasional feature. Dysæsthesia and paræsthesia often annoy him, so that he complains of undue discomfort produced by the contact of his clothing, or of vague sensations and feelings of weight and tiredness, especially in the lower extremities. Abnormal exhaustion after no apparently sufficient effort is referred to "malaria," or some other vague cause. Certain additional perverted sensations lead to a condition of hypochondriasis, which often causes the patient to think he has appendicitis; or annoying sensations in the legs and feet suggest locomotor ataxia. In the large number of individuals aggravating joint pains of an irregular nature are taken for rheumatism or gout, and there may be urinary indications of the same.

Many have first complained of what the writer believes is an early symptom of cerebro-spinal ischemia—cramps in the lower extremities. In some, this painful manifestation often occurred at night, after the slightest daily fatigue. The posterior leg muscles seem to be the favorite locality.

While much has been written about vertigo, I do not think its importance as an indication of progressive arterial occlusion has received due attention.

For a long time before troublesome, or even incapacitating, symptoms have developed, the pre-senile individual is apt, under unusual cardiac stimulation, to become giddy; and this often has no other origin than an excited dispute, attendance at an absorbing play, or the temporary effects of extreme heat or cold; a sudden glance forward, or the act of bending over to tie one's shoe, may too easily cause confusion and slight tottering. Vertigo of this kind is always subjective, and may be termed *postural*, that is to say, it is present even when the individual closes his eyes or suddenly changes his position, and is not of the kind which may be said to be external, and so often associated with Ménière's disease. While it is undoubtedly at times aggravated by gastrointestinal disorders, in which intestinal autointoxication and constipation occur, it exists long after these conditions have been removed.

A large number of men present a constant vertigo which may be recognized as an antero-posterior variety; that is to say, it is always induced when the patient lays his head upon the pillow, or when he looks at an object above him, or when he bends over.

The initial disturbance has been ascribed by patients to "the blood flowing from the front to the back part of the brain"; and there has been a sort of culmination, and afterward a subsidence, when the individual became adapted to his new position. Consciousness is never lost, and the state is not a persistent one, except in the matter of its frequent and annoying recurrence. Attempts at adjustment are attended by more or less cardiac activity, but there is little or no change in color.

Pre-senile insomnia is usually that dependent upon an irritable brain. The patient is exhausted toward the latter part of the day and seeks his bed soon after dinner, and after a short period of sleep awakens, or else does so at a very early hour of the morning. In both cases, the awakening is sudden

and complete, and he is tortured by a veritable kaleidoscope of active thoughts.

There can be no question but that a pre-senile person, so far as the matter of nervous disturbances are concerned, is likely to be influenced greatly by excesses in diet, or by the indulgence in alcohol, tobacco or venery. The indications to be borne in mind are the avoidance of agents that produce rapid and repeated determination of blood to the brain, and which put too much work upon the heart. For this reason, alcohol which is taken regularly is much worse than where the drinking is occasional. The use of "pick-me-ups" or "cocktails" is especially injurious, for this kind of tippling induces not only gastric disturbances, but repeated cerebral flushes, which do more harm than the ingestion of a considerable amount of alcohol at a time.

The rôle played by tobacco in the causation of a pre-senile state is an important one, and while small or moderate quantities of nicotine stimulate the heart excessive amounts not only affect the circulation detrimentally, but undoubtedly induce a paresis of the cerebral arteries with resultant degeneration. While many of the narcotic effects of tobacco poisoning occur in men of all ages, there seem to be certain specific symptoms associated with the so-called "tobacco heart" and with undoubted pre-senile tissue change, and these are other than circulatory.

Vertigo of the kind described which persists for a long time, even after tobacco has been given up, is but a suggestion of how deep the mischief may be. The confirmed smoker is too apt to resume the habit, and degeneration is sooner or later the only ending. While, of course, the capacity for venery is in large measure, in some individuals self-limiting, if abused it may result in so frequent a spasm of the entire vascular system of the brain as occasionally to induce an almost epileptiform state. This repeated strain upon the cerebral arteries of course induces further organic disease.

So far as the treatment and antagonism of presenility is concerned, the cutting off of all possible bad habits will, of course, suggest itself. Absolute abstinence, though, is sometimes as bad as excessive indulgence in men who are habituated, and it cannot be denied that the lack of the customary stimulants has precipitated a condition of affairs which might have been delayed by less radical measures.

The taking of alcohol, in any form, must then be regular, after eating, and always well diluted.

While the medical management of this condition is one about which there is little to be said, each individual case needing different care, reference may be made to the advantages of a modified Nauheim treatment. A decidedly beneficial result is apt to follow the judicious use of a hot saline bath, the effect upon the circulation being quite as prompt and serviceable as that obtained by the expensive and troublesome effervescing bath.

Many cases of natural breakdown and enfeebled volition are undoubtedly regarded and treated as examples of neurasthenia (that most protean and elastic of all terms) whose symptoms express a large number of pathological conditions. It is quite probable that the pre-senile change and its nervous disturbances are like the disease with the pedantic name, nothing more than the result of a number of enfeebling factors.

44 EAST TWENTY-NINTH STREET.

Cocoanut Butter.—Cocoanut butter is now produced in Mannheim, Germany, at the rate of ten tons a day. It contains 99 per cent. of fat, while ordinary butter has only 85 per cent. It is said that it will keep for three months.

CLINICAL REPORT OF A SECOND SERIES OF TWELVE CASES BENEFITED BY BOTTINI'S PROSTATOTOMY.

BY RAMON GUITÉRAS, M.D.,
NEW YORK.

SINCE the publication of a previous series of twelve cases operated upon by Bottini's method, I have been surprised to see the good and permanent results that have been obtained by this method, and the freedom of this operation from danger, when performed in selected cases, with due care as to the details of the technique.

It is easy to see that considerable improvement may follow prostatotomy in cases in which there is no marked enlargement of the prostate as felt by rectum, and in which the floor of the prostatic urethra is but slightly elevated, and the bladder in good condition. On the other hand, it is surprising how great the improvement has been in cases in which the gland was very markedly enlarged, as testified by rectal palpation, in which the posterior urethra was elongated and distended, and the bladder badly diseased.

It is difficult to conceive why an operation consisting simply in burning linear scars in the floor and sides of the prostate gland, and followed by the casting off of sloughs from the edges of the furrows thus made, should cause such a reduction of the urinary obstruction, and such a contraction of the gland. Clinical evidence, however, supports the truth of this statement. It is possible that the cutting off of the blood supply of the prostate by this measure tends to cause an atrophy of the gland, although on examining prostates removed by prostatectomy or at post-mortems we are struck by their slight vascularity, the blood supply being principally outside of the gland. When we see cases, however, in which the amount of residual urine was from six to nine ounces before the operation, and but half an ounce after it, while in cases of complete retention the residuum is often reduced to from one to four ounces after Bottini's operation, we must acknowledge that the obstruction is considerably reduced by this procedure.

One may think, *a priori*, that the contractile power of the vesical sphincters is reduced by the Bottini operation, but I have found, on the contrary, that it seems to be improved after prostatotomy; for in many cases incontinence is cured by this operation, and I know of but one case in which incontinence appeared for the first time after the prostatotomy.

It is an acknowledged fact, therefore, that Bottini's operation improves the urinary function, as evidenced by the reduction in the amount of residual urine, and by the increased tone of the vesical sphincter; but it may be well to say a few words concerning the sexual function after prostatotomy. It has been supposed that the sexual function is destroyed by the operation, but this drawback was considered as of but little consequence, on account of the advanced age of most patients operated upon. Besides, the urinary symptoms are so distressing in these cases that the surgeon thinks more of the urinary than of the genital tract, in considering the advisability of an operation of the sexual organs.

It may be well to state, therefore, that patients are not always incapacitated for sexual life by the Bottini operation. This was shown in one of my cases of the first group, a man aged sixty-seven years, who was operated upon two years ago. He was then suffering intensely from urinary symptoms, and had six ounces of residual urine. Recently he presented himself at my office to be treated for a venereal disease that he had contracted during intercourse. This man considered himself cured of his prostatic trouble.

The patients in the first series of cases were operated upon under a local anæsthetic, eucaine or cocaine, or else under nitrous-oxide gas. Ether was used in most cases in the second set, although I still advocate the use of nitrous-oxide gas as the best anæsthetic in these operations. Most of the patients whose histories have been reported in the first group are still alive and well. The others have passed from my observation, but I have not heard of any death among them.

The following are, in brief, the histories of the second series of twelve cases operated upon by Bottini's method. I have been obliged to condense the histories from my records, in order to make the articles of moderate length, but I have endeavored to give all the essential features of each case.

Case I.—Farmer, aged seventy-five years, family history negative, except rheumatism. No venereal history. For twelve years past he has had difficulty in urinating, with tardy, weak stream and sometimes pain. Two years ago he had an attack of acute retention, lasting for two weeks and requiring catheter four times a day. Then he began to urinate spontaneously, and the catheter was discontinued, although the stream remained small and there was considerable pain and tenesmus. Six weeks before admission, he had another attack of acute retention lasting for two weeks, necessitating catheterization every four hours. Spontaneous urination was again possible, but since then the frequency has increased, the stream become smaller, and there was more pain and tenesmus than ever before. During his attacks of retention he suffered considerably from urethral fever, accompanied by chills and a rise of temperature.

The kidneys were found normal on palpation. The prostate was enlarged laterally to the size of a hen's egg. There was a stricture of the meatus and a marked impediment in the prostatic urethra. The residual urine was six ounces. There were traces of albumin, some pus, some bladder epithelium, and some hyaline and granular casts in the urine. The operation consisted of a posterior incision, 4 cm. long. The battery gave out during the operation, causing a twist of the blade during the extraction of the instrument. The post-operative period was characterized by a reaction on the second day, with a temperature going up to 104° and a pulse of 128; but these symptoms subsided, and the remainder of the convalescence was uneventful. The patient left the hospital, and in a letter eighteen months later stated that he was perfectly well, and that he did not have any more attacks of retention. His prostate was large, but his kidneys were in a fair condition, and if he should have any further trouble, I should recommend enucleation. I am sorry not to be able to report the decrease in the amount of residual urine since the operation.

Case II.—Merchant, aged seventy years, without any venereal history. Three months before examination his bladder began to trouble him, the frequency of urination gradually increased, and there were occasionally pain and tenesmus. Three weeks before examination he had considerable difficulty in passing urine, but this improved somewhat, until three days ago, when he had an attack of acute retention, and was catheterized. At the end of twenty-four hours, not having passed any more urine, he was sent to me for operation. I catheterized him, and drew off sixteen ounces of urine. On the following day he entered the hospital, still suffering from [illegible] retention. On examination his kidneys were [illegible], the right lobe of the prostate was enlarged [illegible] its ordinary size, the left not so markedly. The bladder was found to be full of urine, of which sixteen ounces were withdrawn. The urine was free from albumin and contained pus and bladder epithelium. The patient was allowed to remain in the hospital for nearly three weeks, and was treated for his acute retention and cystitis. He was catheterized every six hours, his bladder was washed out with boric-acid solution twice daily, and he was given lithia water and benzoate of soda and belladonna. In addition, he received bladder irrigations every other day with silver-nitrate solution and rectal douches of salt solution night and morning. At the end of three weeks he passed from one to three ounces of urine spontaneously, and secreted about fifty or sixty ounces daily. The residual urine varied from fourteen to twenty-two ounces. Bottini's operation was performed under ether, using three incisions, one posterior 4 cm. long, the other lateral on the right side 3.5 cm., on the left 3 cm. The after-treatment included the use of the catheter permanently, until he urinated spontaneously; urotropin, 10 grains three times a day, and water *ad libitum*. The reaction, with a temperature of 103, a pulse of 138, and a respiration of 30, took place on the second day. The convalescence was marked on the third day by a pulmonary congestion. On the evening of that day he passed fourteen ounces of urine spontaneously at one time. On the sixth day he showed a residuum of but two ounces, and from this time on his recovery went on uneventfully. The patient continued to drink large quantities of water, and to pass large quantities of urine. Two weeks later the use of the catheter was omitted, and on leaving the hospital he had less than an ounce of residual urine. It is almost incredible that a patient who entered the hospital with complete retention, and who, after three weeks' treatment could only pass two or three ounces spontaneously, was so improved after Bottini's operation that he could pass sixteen ounces at a time spontaneously in less than a week after the prostatotomy, and his residual urine was reduced to less than two ounces.

Case III.—Painter, aged seventy years, without any venereal history. Had been suffering for four years from frequency of urination, tardiness of stream, and some heaviness and pain in the hypogastric and lumbar regions. He had been troubled with a certain degree of incontinence, and had been passing his urine from six to eight times during the day, and about six times at night, before he applied for relief. The urine was passed with difficulty, and the stream was small. When he presented himself, he was suffering from overflow incontinence, following an attack of retention. His physician had told him that the retention was due to a stricture.

On examination, the bladder was found distended, and could be felt as a tumor in the pelvis. The prostate by rectum was felt to be enlarged to about one and one-third its normal size, and firm in consistency. The urethra was of normal caliber until the prostatic portion was reached, where an obstruction admitting only a No. 8 French olive-tipped, elastic-gum catheter was found to be present. Sixteen ounces of urine were withdrawn at the time, the patient was put to bed, and given hot rectal douches twice daily, and hot sitz-bath daily. Urotropine [illegible] were also prescribed. At the [illegible] able to pass one and one-[illegible] urine spontaneously, but still had some [illegible]. He complained of pain, and twelve [illegible] ounces of urine were withdrawn. During the night there was some incontinence and two or three ounces of urine were passed. There was a great deal of pain and tenesmus, for which symptoms an opium and belladonna suppository was given. In the morning

twelve more ounces were withdrawn. He was then kept on the same treatment and was catheterized every six hours for a week. His urine had a specific gravity of 1,026, showed some shreds, and a small amount of albumin and of pus, but no casts and no bladder epithelium.

Although the tenesmus and spasm were much reduced during the week, it was difficult to introduce a catheter larger than No. 14 French.

At the expiration of the preparatory week, the Bottini operation was performed under ether. The instrument encountered resistance at 7 inches beyond the meatus, but on elevating the hips and depressing the handle of the instrument well, it entered the bladder, after some force had been used. A posterior incision 3½ cm. long, one through the right lobe 2½ cm., and through the left lobe 2 cm. long were made, and a catheter tied in after the operation.

The post-operative period was characterized on the first day by a reaction, with rise of temperature to 103°, and later to 104°, with a pulse varying from 110 to 115. Toward the evening of the second day the alarming symptoms subsided, but there were considerable pain and spasm, while the catheter *à demeure* was *in situ*. On the fifth day there was a slight rise in temperature, and the catheter was removed; but the urine was passed with great difficulty and with much spasm and pain. During all this time the patient had been passing a sufficient quantity of urine. On the sixth day the catheter was introduced once more and retained, No. 14 French being passed. An attempt at catheterization on the sixth day, before the introduction of the permanent catheter, resulted in pain, hemorrhage, and great spasm. The temperature and pulse, and the tenesmus and pain, gradually improved for a week after that, and the patient left the hospital at the end of four weeks very much improved. He urinated four times a day, and twice at night; his pulse and temperature were normal, and three weeks later, when seen for the last time, his residual urine measured two and one-half ounces. Since then he has been on a mixture containing tincture of belladonna and sodium benzoate.

Case IV.—Printer, aged sixty-seven (City Hospital.) There was a past history of rheumatism and of syphilis, and for the past two years the patient had had a sense of weight in the pelvis, as well as occasionally attacks of frequent urination. Micturition was accompanied by some burning. Three months ago, however, the symptoms became fixed, and gave him more trouble than before. The frequency did not abate as usually, and he presented himself for relief. He said that he had no control over his stream, passed urine very frequently, and with some difficulty, every hour during the day, and about ten times at night. There was no pain, but some burning. On examination there was pain on pressure over the right kidney, a varicocele was found on the left side, the prostate enlarged to one and one-half its size, equally on both sides, and a No. 18 French sound encountered obstruction at the prostatic urethra, but passed into the bladder. The residual urine measured three ounces. The urine showed some pus and bladder epithelia, but no kidney lesions.

The Bottini operation was performed under ether. The incisor entered quite easily, and three cuts were made. A posterior cut 3¼ cm., an anterior cut 2½ cm., and two lateral cuts 2³ cm. each. The post-operative reaction was almost absent, the temperature and pulse not being over 100, and he passed urine without any difficulty on the second day. The recovery was uneventful. He passed sloughs for four weeks after the operation. At the end of three weeks he had three drachms of residual urine. Rest in bed, urinary antiseptics, and anodynes, and later bladder irrigations were used, and he was very markedly improved. This was an ideal case for the Bottini operation.

Case V.—Cuban planter, aged fifty-eight, without any venereal history. For seven years he had gradually increasing frequency in urination, pain and difficulty in passing urine. In addition, he had been suffering for some time from chronic gastritis. He was losing flesh and had a slight rise of temperature. A consultation among the physicians of his city resulted in a diagnosis of malignant abdominal tumor. When he consulted the writer, the patient stated that he passed his urine every half-hour during the day, and frequently at night. He had also some incontinence, and his urine was passed with a great deal of difficulty, straining, and tenesmus. He never passed more than two ounces at a time.

On examination, he was found to be cachectic, with a temperature of 102° and a pulse of 100, some tenderness over the kidney, a distended bladder, a prostate which was enlarged to about one and a half its normal size, and a urethra that admitted a No. 12 French catheter with great difficulty. Twenty-four ounces of the residual urine were withdrawn, and the total residuum was estimated to be about twice this quantity. The bladder was emptied by catheter gradually at intervals in the usual manner, removing a portion of the urine each time. The difficulty in passing the catheter was probably caused by urethral spasm. When the bladder had been emptied, a second examination of the prostate showed this organ's outlines more clearly. It was found that the urethra was elongated to the extent of one inch. The urine contained albumin, pus, and granular and hyaline casts.

Preparatory palliative treatment was used for two weeks. He was catheterized three times a day, and his bladder was washed out every other day with nitrate of silver. In addition he received hot rectal douches and urotropin. Under this treatment he began to pass small quantities of urine. On one occasion, however, he failed to appear at the office at the regular catheterization, his bladder filled up, and his temperature rose to 103°, his pulse to 110. He attempted to catheterize himself with the result of producing considerable hemorrhage from his urethra. His bladder was found dilated above the umbilicus, sixteen ounces were drawn, and he was sent to the hospital, where he was treated for two weeks longer by palliative methods. During this time the symptoms of cystitis improved somewhat, but the catheter had to be retained and plugged, the plug being drawn out every two or three hours.

Cystoscopy before the operation showed a well-defined rounded and elevated prostatic base, a markedly trabeculated and congested bladder, with considerable detritus hanging from the walls and some large slugs emerging from the mouth of the right ureter indicating a pyelitis. Bottini's operation was performed. Three cuts were made, the posterior one through the middle lobe being 3¾ cm. in length, and the lateral ones through the right and left lobe respectively 3¼ cm. each. After the operation a No. 18 French catheter was passed to be retained, and plugged. There was practically no post-operative reaction. A sufficient amount of urine was passed from the first, and the patient passed the danger point on the third day without any marked rise of temperature or frequent pulse. On the fifth day the urine was bloody, and there was frequent desire to urinate and a great deal of spasm. Later the urine became clear and a large slough was found in it, showing that the bleeding had been due to its separation.

On the sixth day the catheter was removed, to be passed every three hours, and irrigations with boric acid twice a day and of nitrate of silver every other day were ordered. The remainder of the recovery was uneventful. During the second and third week at the hospital he was catheterized five or six times a day, and passed from 75 to 90 ounces daily with and without catheter. On leaving, he was told to catheterize himself twice daily, as his residual urine was but four ounces at that time. It is probable that in six weeks longer the residuum will have still more diminished, and it is to be regretted that the patient would not consent to intravesical enucleation as he was undoubtedly more suited for this operation than for the Bottini.

CASE VI.—Machinist, aged sixty-five years, single, German. No venereal history. Has always been a hard-working man. For the past few years he has had frequency of urination, gradually increasing, and most severe in the spring and the fall of the year. He was obliged to get up once and sometimes twice during the night to pass his urine.

Six weeks ago the frequency of urination became more marked than ever, and was accompanied with a good deal of pain and burning. He noticed at that time that his urine smelled badly. Three weeks later after exposure to wet and cold, the frequency increased still more, and there was considerable difficulty in passing the urine, which was sometimes bloody. The stream seemed to lack in force. These symptoms increased until four days before admission, when he could not pass any urine. He seemed to have lost control of it and it dribbled away. He complained of pain in the rectum and at the end of the penis, and of a sense of fulness in the lower part of the abdomen.

On examining him, he was found to be a tall, well-built man. His temperature was 100°, his pulse 88. The kidneys were not tender to palpation, the bladder was markedly distended half-way up to the umbilicus. The prostate was found by rectal palpation to be enlarged about one and two-thirds its original size, and the bladder to be tender over the trigone. The urine was alkaline, of foul odor, contained 1 per cent. of albumin, and a large amount of pus, together with some few granular and hyaline casts. A No. 26 French sound entered the urethra for six and one-half inches. No stone was found with a Thomson searcher. All his urine was residual, as at the time he was suffering from an attack of retention. A No. 12 French catheter was introduced and sixteen ounces of the residuum withdrawn. He was then catheterized at intervals of three hours, and twelve ounces of urine were withdrawn each time, until his bladder was emptied. Then the catheter was used every six hours. He was given salol, water *ad libitum*, and milk diet. His bladder was washed out, as in the other cases, with boric-acid and silver-nitrate solutions, and hot rectal saline douches were given to reduce the prostatic congestion. This general and local treatment was continued for one month, at the end of which time he was passing from 25 to 30 ounces of urine spontaneously in twenty-four hours, and the amount of residual urine was nine ounces. The quality of the urine had also improved very much, as there was scarcely any albumin, no casts, and much less pus.

Bottini's operation was performed under ether anæsthesia. Three cuts were made, a strength of 45 ampères being used. The posterior cut was 4 cm. long, the two lateral ones 4 cm. each. A retained catheter was introduced. The reaction came on the next day at 6 P.M., with a chill and a rise of temperature to 103°. On the following morning these alarming symptoms had subsided. The permanent catheter was removed on the fifth day, and the further recovery was uneventful. The patient remained in bed for three weeks, at the end of which time he had but one and one-half ounces of residual urine. Two weeks later, after leaving the hospital, the residual urine was still one and one-half ounces. This case shows how a patient with complete retention can in a short time, after an operation, pass his urine spontaneously, discarding the catheter. Enucleation, which was indicated in this case from the size of the prostate, might have been fatal owing to the bad condition of the kidneys and bladder. Possibly later a prostatectomy could be successfully performed upon this patient.

CASE VII.—Manufacturer, aged sixty-seven years. Family history negative. For ten years past he has had difficult and frequent micturition, with some retention. Four and a half years ago he became worse, requiring frequent catheterization. At the same time he was suffering from attacks of so-called malaria, which were probably urinary fever, lasting one or two weeks at a time, and completely prostrating him. These attacks became so severe that he had to remain in bed for two months with a retained catheter. Since then he has had complete retention and has been living a catheter life. He washed out his bladder four times daily with solution of nitrate of silver. Four months ago he has had an attack of orchitis, which has since then subsided, but he still complains of heaviness in his testicle. At the time of admission he had overflow incontinence, passed his catheter five or six times a day, whenever he had a desire to urinate, and found usually about twelve ounces in his bladder.

On examination, his kidneys were not sensitive to pressure. A 16 F. sound passed into the bladder caused some bleeding; the prostate was found to be twice its normal size, and the urine contained slight amount of albumin, a great deal of pus, and some hyaline and granular casts. On introducing the cystoscope under nitrous-oxide gas, it was found that the instrument did not enter the bladder, but that it had passed what seemed to be the prostatic base in the rectum. The instrument rotated in what probably was the prostatic chamber.

The bladder was washed out through a 16 F. soft-rubber catheter, and the Bottini incisor was introduced. It stuck in the posterior urethra, but on depressing the handle, and on pushing the beak into the bladder with some force, it entered, was turned downward, and caught behind the vesical base. It was evident on rectal palpation, then, that the vesical base was considerably farther up than the rectal. A posterior incision 4 cm. long and two lateral ones of the same length were made. It was difficult to rotate the instrument, and after the operation the catheter that had been previously used to wash out the bladder could not be introduced. Accordingly, ether was given, a tunneled sound introduced into the urethra, and a perineal urethrotomy was performed. The forefinger introduced into the prostatic urethra showed an enormous right lobe converging beyond the middle line of the urethra, while the left lobe was concave and overlapped the right lobe above and below. The bladder was so far up that the tip of the finger could not be made to enter, for it came into contact with the middle lobe. A perineal drainage tube, 38 F., was introduced through the tortuous posterior urethra into the bladder, but did not drain well. It was left *in situ*, however. The tube had to be pushed in for eight inches beyond the surface of the perineum before the urine would flow. The 38 F. catheter had not entered easily on account of the curve, and not as much water came away through it as was put in, which led me to think

that the left lobe had been cut in its most shallow part, the cut going through the cellular tissues.

Strychnine, atropine, hot rectal douches, water to be drunk in small quantities, and urotropin were ordered. The post-operative reaction came rapidly on the evening of the day of the operation, the temperature rising to 103°, the pulse to 112. The patient did not seem to be draining well, and had some pain in the region of the prostate. After some fluctuations in temperature and pulse, he passed the danger point on the third day, when he passed eighty-six ounces of urine in twenty-four hours, as compared to twenty-five ounces for the previous day. The former amount diminished somewhat on the next day, and a diuretic mixture containing niter and potash was given. He also had opium and belladonna suppositories for spasm. The temperature continued between 98° and 100°, the amount of urine between eighty and ninety ounces in the twenty-four hours. Urotropin and salol were continued, and the perineal tube was removed and a retained catheter introduced at the end of a week. At the end of four weeks the patient was able to pass large amounts of urine spontaneously in amounts of two to ten ounces at a time, passing sometimes twenty or thirty ounces at night. His last letter, after leaving the hospital, showed that he had only four and a half ounces of residual urine when he catheterized himself night and morning.

This is another remarkable result after a Bottini operation in a case where there had been complete retention for four years, and where a prostatectomy should have been performed had the patient's condition warranted it.

Case VIII.—Teacher, aged fifty-five years, without any venereal history. For two or three years he had suffered from frequency of urination, six to nine times during the day, and two or three times at night; occasional attacks of cystitis. Six weeks ago he began to have dribbling, and could not empty his bladder completely, but passed small quantities, with some burning.

On examination, his left kidney proved tender to the touch. The bladder was distended to above the umbilicus; the prostate was uniformly increased in size to about one and one-half. A 26 F. sound passed into the urethra for six and one-half inches. A Thomson searcher passed into the bladder, riding over an impediment at the prostatic urethra. A 15 F. catheter passed into the bladder and drew urine at nine inches from the meatus. Sixteen ounces were withdrawn, and the bladder tumor did not decrease much in size. The same preparatory treatment as had been used in the other cases was given, including gradual emptying of the bladder at intervals, bladder lavage, and salol.

The urine showed no albumin, a few casts, but was foul smelling. The palliative measures were used for a week, the patient being kept in bed. At the end of that time he could pass from two to four ounces of urine, but had still twenty-four ounces of residual urine.

Bottini's operation was performed under ether anæsthesia. The incisor was introduced, and three incisions were made. A posterior one 3½ cm. long, and two lateral ones, each 3 cm. A 15 F. catheter was inserted to be retained. The reaction came in the evening of the day after the operation, and was fairly mild in character. The danger point was passed at the end of the second day. The amount of urine passed gradually increased, and the remainder of the convalescence was uneventful. For two weeks he passed sloughs of various sizes. There was no high temperature, and the catheter was removed. He could then pass from four to six ounces of urine spontaneously at a time. Two months after the operation he had nine ounces of residual urine. He was suffering then from interstitial nephritis. I have not seen the patient since, but know that he has died from his kidney trouble. This operation was performed two years ago. His bladder was atonic, and the decrease of the residual urine to nine ounces showed a considerable gain. He was a subject for a second operation, but on my last visit I did not dare to operate on account of his nephritis.

Case IX.—Merchant, aged seventy-two years. Difficult and painful micturition for several years; treated by a number of physicians with palliative measures. Has had attacks of epididymitis, and was usually better in summer than in winter. Principal symptoms: Difficulty in urination, pain in the pubic region and occasionally in the perineum, and tenesmus. He passed his urine every few minutes, day and night, and the act was accompanied with a great deal of pain and tenesmus. He felt that something radical must be done.

On examination his kidneys were slightly tender on pressure; both lateral lobes of the prostate were found enlarged, the right being the larger one. The bladder was tender on pressure over the trigone. The urine showed traces of albumin, pus, and casts. The urethra was of good caliber, 29 F. A stone searcher passed the prostate and detected no stone. The amount of residual urine was nine ounces.

The patient was given a mixture of belladonna and sodium benzoate, and a 12 F. catheter was introduced and retained. The patient was operated under ether anæsthesia. The bladder was washed out through a 16 F. catheter, the Bottini instrument entered with difficulty, the patient's hips having been raised while the instrument was pushed forward through the prostatic urethra. A cauterization 4 cm. in length was made through the floor, one 3½ cm. long through the left lateral lobe, and one of 3 cm through the right. The instrument seemed to catch in the posterior urethra, and was withdrawn with some difficulty.

After the operation the catheter that had been passed before could not be reintroduced, and a smaller one was passed and tied in. This is explained by the fact that the urethra was tortuous, and the prostate had been split in cutting from the lowest point. The reaction, in the shape of a chill, a temperature of 101° and a pulse of 100, came during the first day, and subsided on the second. On the third day he had passed the danger point and had secreted eighty ounces of urine in twenty-four hours. On the fourth day the catheter was plugged, the plug being withdrawn at intervals for urination. The catheter was removed on the sixth day. On the seventh he passed eighty-eight ounces of urine spontaneously. The same after-treatment was used as in the other cases. For two weeks longer he remained in bed, and for some time afterward complained of pain, frequency, and tenesmus. He was really a case for prostatectomy, but this operation was contraindicated at the time by his condition, as his urine showed the presence of pyelitis and nephritis. He still has cystitis, is a most marked type of neurasthenic, and will probably be a candidate for another operation—a prostatectomy if he gains sufficient strength, a Bottini if otherwise. A perineal section after this operation would have given him freer drainage and would have diminished the amount of anxiety. From the surgeon's viewpoint this case has shown marked improvement after operation, as the catheter now enters more freely, and the amount of residual urine has been reduced to half an ounce from nine ounces, and I think that the patient will continue to improve even if not operated upon again.

Case X.—Painter, sixty-eight years, without any venereal history. Well until nine years ago, when he noticed difficulty and frequency in urination. For the past few weeks he has had considerable difficulty in passing his urine, and his stream has been small, weak, and at times there has been dribbling and pain in the perineum and neck of the bladder. He never has had retention. On admission his principal symptoms were difficult and painful urination, half a dozen times during the day and as many at night.

On examination, his kidneys showed no tenderness, and suprapubic percussion and palpation were negative. The right testis was softer than the left, the prostate increased to one and one-third its original size, and the urethra offered obstruction at six inches to a 19 F. bougie à boule. A 16 F. sound passed into the bladder, going over the impediment in the prostate. He had four and one-half ounces of residual urine, which showed a trace of albumin, no casts, and a small amount of pus.

This appeared to be an ideal case for a Bottini operation. The kidneys were normal, the bladder in good condition, and the prostate not greatly enlarged, principally in the floor of the prostatic urethra. The patient had not reached the point when the bladder begins to give out and the kidneys begin to be involved. The patient was given the usual preparatory treatment for a week before the operation, including urotropin, water *ad libitum*, and bladder injections.

A Bottini operation was then performed. The incisor was easily introduced under ether anæsthesia. Three incisions were made through the gland, the strength of the current being 45 ampères. The first incision, through the floor of the urethra, measured 3 cm., the other two, through the lateral lobes, 2½ cm. each. No retained catheter was employed. Urotropin and large amounts of water were ordered. There was no reaction, and the patient did well from the time that the effects of the ether passed away. On the second day an attempt to pass a catheter was without success on account of spasm of the sphincter muscle. The urine was passed spontaneously from the first day, and the bladder was left alone, but urinary antiseptics were given internally. During the weeks after the operation, the temperature ranged from 98° to 99°, the pulse from 64 to 74. He passed a few large shreds during the first, second, and third weeks. At the end of that time the residual urine measured only two ounces, and when I saw him last, it was only one and a half ounces. His symptoms were all relieved by the operation, but he has now some urethral insufficiency, showing itself by dribbling independently of micturition—the first case of the kind that has come under my observation.

Case XI.—Journalist, aged sixty-four years, with a history of urethritis when young, accompanied by a cystitis. Had had gradually increasing frequency of urination for five years. This was especially marked for the past two months, and was associated with burning. He was passing urine every two hours during the day and about every hour at night.

On examination, his kidneys were negative, and suprapubic percussion and palpation showed nothing. The prostate proved to be slightly enlarged, by rectal palpation, as though it had been the seat of a prostatic abscess. A 28 F. sound entered the bladder, but a catheter introduced found four and a half ounces of residual urine. When the end of the sound was caught behind the vesical base of the gland, and its tip palpated by rectum, it was noted that the rectal and vesical bases were about the same distance back. It was therefore probable that we had to deal with a prostatic bar—a most favorable case for a Bottini operation. The urine showed a small amount of pus, a trace of albumin, and no casts.

A Bottini operation was performed. Under ether narcosis the incisor entered easily. Only one cut was made, and that went through the floor of the prostate, as the gland was not enlarged, and the impediment seemed to be posteriorly. The incision was 3 cm. long. No catheter *à demeure* was introduced.

During the first and the second day he passed but little urine, and was given a mixture containing niter and potash, with the expected effect. There was no reaction, and the patient improved very rapidly. On the third day he was put on the regular diet, and his further recovery was uneventful.

Two weeks after the operation, he had but three ounces of residual urine, and the bladder was washed out every day with boric-acid solution and every other day with silver nitrate. A tonic of strychnine and iron was given, and rectal douches of hot salt solution were used every night. A month after the operation he had but two ounces of residual urine and declared that he felt better than at any other time in ten years. Two months after the operation he had one ounce of residual urine. This was a most satisfactory case of the type that could only be benefited by a Bottini prostatotomy.

Case XII.—Organist, aged sixty-two years. For four years he has had frequency of urination, gradually increasing and accompanied at times by tenesmus and burning. He has had two attacks of retention, one two years ago, and one three months ago, relieved by catheterization. At present he urinates nine times during the day, and five or six times during the night. He complains of pain in the suprapubic and perineal regions, and of ardor urinæ.

On examination his kidneys proved negative on palpation. The prostate as felt by rectum was slightly enlarged and indurated. The vesicles could not be felt. The urine was cloudy, slightly alkaline, contained a trace of albumin, considerable pus, some epithelium, but no casts. His urethra was not much elongated, but there was an impediment in the posterior portion. He had three ounces of residual urine. He was put on the usual preparatory treatment for one week, at the end of which time the Bottini operation was performed.

Three incisions were made, the posterior one 3 cm. long, the two lateral ones 2½ cm. each. No catheter was retained after the operation. There was no reaction to speak of, the temperature not rising above 99°, the pulse not above 90. The after-treatment was the same as in the other cases. On the fifth day, he began to pass sloughs in large quantities, and continued this during the next week. He remained at the hospital two weeks, at the end of which time he had one and one-half ounces of residual urine. One year later he said that he was perfectly well, and the probabilities are that at that time he did not have more than half an ounce of residual urine. This was a case peculiarly suited for a Bottini operation.

Summary.—In looking over the histories of these cases, we see that the patients were all workingmen of good habits from fifty-five to seventy-five years of age. One of them had had urethritis, and two had syphilis many years ago. They all complained of frequency of urination and some pain. Six of them had retention of urine when they applied for operation; two others had had attacks of retention. Five had had incontinence depending upon retention (overflow and incontinence). Three ran a temperature. One suffered from urethral fever. Two suffered from attacks of a epididymitis during the prostatic trouble.

The operation was followed by a reaction in eight of the twelve patients, five of whom had nephritis. This would tend to show that the reaction is more frequent and more severe in patients suffering from

nephritis, and not so frequent or severe when no nephritis is present.

All the patients operated upon, with one exception, said that they felt better, and in all cases the amount of residual urine was diminished by quantities varying from two to seven ounces. Patients who could not pass urine at all, having suffered from complete chronic retention, were able to empty their bladders with the exception of a few ounces.

In the patient who said he was not improved, his frequency of urination was much reduced, and the amount of residual urine reduced from four and one-half to one and one-half ounces in a few weeks. He complained of incontinence due to the operation.

In closing these remarks on the Bottini operation, it will be seen that in these patients, many of whom were operated upon two years ago, there were two classes. The first class had suffered for a long time, they had considerable retention when they applied for treatment, and examination showed their prostates to be remarkably enlarged. In the second class of cases, some of them had had attacks of retention, but the prostate was not much enlarged, as felt by rectal touch, and the urethra not much elongated, although there was an impediment in the posterior portion.

The first class of patients should really have been operated upon by enucleation, but either they feared the operation, or the operator feared that they would not survive it on account of the condition of their kidneys; therefore a Bottini prostatotomy was performed.

The second class of patients was suitable for a Bottini prostatotomy and were properly operated upon by it. All of them were benefited but one, and although he had been thoroughly operated upon, and there was no reaction and a very marked decrease in the residual urine, he afterward complained of feeling worse than before the operation. In performing an operation of this kind, the estimation of the result is different as viewed by the surgeon or the patient. All of these cases were benefited according to the surgeon's idea, in that the amount of the residual urine was greatly diminished. They were all able to urinate spontaneously, and the cystitis had been benefited. Some of the patients, while acknowledging they had better control of their bladders, did not feel they had been benefited much, as they still had frequency of urination and burning, due probably to the cystitis which had not been cured.

The practitioner is apt to think that, the obstruction having been removed, all will go well; but such is not the case. A chronic cystitis which has gone farther than the superficial layer, and has become interstitial in a trabeculated bladder containing diverticula, cannot be brought to the condition of a youthful viscus; and this is not hard to realize when we consider that in women with no obstruction and a urethra but one and one-half inches long, rebellious forms of chronic cystitis occasionally exist which defy all treatment.

75 WEST FIFTY-FIFTH STREET.

Injections of Creosote and Guaiacol in Pulmonary Tuberculosis.—G. Jucci and G. Bazzicalupo combined guaiacol with creosote, in order to render the injections of the former less painful and to make the drug better tolerated. As a result of their experiments, they found that the two substances, united in an oleaginous mixture, could be given in much larger doses than either drug alone. They were well tolerated, had no topical action, were promptly assimilated, and were eliminated through the respiratory tract. The authors do not consider this method a cure for tuberculosis, but they do think that it arrests the progress of the disease, and brings much relief to the patient.—*Gazetta Internazionale di Medicina Practica.*

ON THE TRANSMISSION OF YELLOW FEVER BY VESSELS, AND ITS BEARING UPON QUARANTINE REGULATIONS.*

BY EDMOND SOUCHON, M.D.,
NEW ORLEANS, LA.,
PRESIDENT LOUISIANA STATE BOARD OF HEALTH.

IN a remarkable article, with a somewhat similar heading, by Dr. Alvah H. Doty, Health Officer of the Port of New York, published in the MEDICAL RECORD of October 26, 1901, the writer, after making many statements, concludes as follows: "In accordance with the above views, the treatment of incoming vessels from ports infected with yellow fever becomes very simple; if they are five days or more in transit, and all on board are found to be well after a careful inspection and the use of the clinical thermometer, the vessel, its passengers, and crew shall be released without further detention or treatment. If the vessel has been less than five days in transit, all on board who cannot present satisfactory evidence of immunity should be removed and held for observation until the completion of a period of five days from the time of departure from the infected port, and then released only after a careful inspection. When yellow fever is found on incoming vessels, the procedure should differ only so far as it concerns the removal of the patient to a properly constructed hospital or apartment for treatment."

I will not here take up all the points raised by the eminent sanitarian, but will simply present in rebuttal the following cases, which speak eloquently and incontrovertibly for themselves. They are clinical facts which theories, past or present, will or will not explain; but as facts they stand in all their might and brightness and must always be reckoned with under most fearful penalty.

This array of cases was gathered to demonstrate the danger resulting from vessels from infected ports which, although having developed no yellow fever in transit for many days, yet, at the last moment and after disinfection, have developed infection. The cases were gathered on the axiomatic ground that one positive is better than a million of negatives. They bring the demonstration of the danger much nearer home even than do Dr. Doty's negations.

Few of the vessels were less than five days out when they developed yellow fever, but on several the last case on board developed while still in quarantine, and when more than five days had elapsed from the date of departure. Many of the vessels were more than five days out when they developed yellow fever. All the vessels herein mentioned, if treated according to Dr. Doty's theory, would have carried infection, at least in Southern ports.

Seven such vessels were stopped at the Mississippi River Quarantine Station in very recent years, not to speak of remote years—the *Denia* in 1892; the *Tampican* in 1896; the *William Cliff* in 1898; the *Whitney* in 1899; the *Sardinia* in 1899; the *Hugin* in 1900; the *Electrician* in 1900. Two such vessels were stopped at Mobile—the *Lombard* in 1899 and the *Bodo* in 1900.

We must not lose sight of the fact that yellow fever develops and spreads with difficulty in Northern climates, whereas in the South the least spark that may pass harmless through a Northern port will set the Southern country on fire. What is true and harmless for New York in Dr. Doty's statements may not be, and I do not believe is, true for New Orleans, Mobile, and Galveston.

If I could gather some thirteen cases in the meager

*Read at a meeting of the Louisiana State Board of Health, November 29, 1901, and officially approved by resolution of the board.

literature of the day on the subject, I am satisfied that if proper records were kept at all quarantine stations, quite a respectable number of cases would be found in a run of five or ten years. I have made no search for cases of vessels which developed infection in transit, because I consider the demonstration by clinical facts that non-infected vessels from yellow-fever ports could develop infection after disinfection, and at the port of arrival, was proving a much greater danger than the others and was showing conclusively the importance of detaining five days after disinfection, at Northern ports, passengers who are not bona-fide residents of the North and who might come South and infect it.

NON-INFECTED VESSELS FROM PORTS QUARANTINED AGAINST YELLOW FEVER, WHICH DEVELOPED YELLOW FEVER AFTER DISINFECTION AT QUARANTINE STATION.

1880—Bark *Excelsior*. Sailed from London February 17, 1880; arrived at Rio April 13; left Rio May 10; arrived at Mississippi Quarantine Station, June 25 (Wilkinson), having been on the voyage forty-five days; no case of sickness occurred at Rio or on the voyage; she was disinfected on June 26, and following (Wilkinson). She was detained twelve days altogether, up to about July 4. (?) Arrived at New Orleans on July 5; on July 7, at 8.30 P.M., John Kinney was taken sick; on July 10, in the morning, he was removed to Touro Infirmary; he developed a genuine case of yellow fever; he died; the bark was returned to the Quarantine Station on July 10; three more cases developed after the return at the Quarantine Station; two died. (Report of Louisiana State Board of Health, 1880.)

1890—British steamer *Curlew*, from Rio, with rock ballast; sixty-eight days out from Rio; no sickness was reported at port, *en route*, or on arrival; cleaned July 22 to July 23; disinfection completed July 25, in the afternoon; one and one-half days after completion of disinfection, one case of yellow fever developed July 27, in the early morning, before day; the disease was probably contracted between July 22 and July 25; incubation between five days and one and one-half days. (H. R. Carter, United States Quarantine Officer, Chandeleur Island in MEDICAL RECORD, March 9, 1901.)

1892—Steamer *Denia*, from Havana, arrived at Mississippi River Quarantine Station August 26, in the forenoon; no record of sickness in port or *en route;* disinfection same afternoon; eight hours after, two men were attacked with yellow fever. (See Report of Louisiana State Board of Health, 1894–95.

—British ship *Chippewa*, from Rio, with rock ballast; sixty-four days from Rio; no sickness was reported in port, *en route*, or on arrival; cleaned July 26 and 27; disinfection completed July 28; one day after, one man, the quartermaster, developed yellow fever at night; he probably contracted the disease between July 26 and 28; incubation three and a half to one day. (H. R. Carter, United States Quarantine Officer, Chandeleur Island, in MEDICAL RECORD, March 9, 1901.)

1898—*Tampican*, from Vera Cruz; developed yellow fever thirty-six hours subsequent to disinfection. (Report Louisiana State Board of Health, 1898–99, p. 73.)

1898—*William Cliff*, from Vera Cruz; developed yellow fever thirty-six hours subsequent to disinfection. (Report Louisiana State Board of Health, 1898–99, p. 73.)

1899—Schooner *R. D. Spear*, from New York to Key West, where she lay unloading during the epidemic of 1899; the crew were not allowed to go ashore, but the captain went ashore every night; she left Key West September 15; arrived at Mullet Key Quarantine September 20; disinfection was completed September 20, at 4 P.M.; three days and ten hours after, on September 24, at 2 P.M., the captain sickened and had a chill; incubation not less than three days and ten hours. (D. M. Echemendia, Quarantine Officer, Tampa Bay Quarantine, Florida Board of Health, in MEDICAL RECORD, March 9, 1901.)

1899—Steamer *Whitney*, from Havana; arrived at Mississippi River Quarantine Station on October 11; disinfection; two days later a case developed, but presented no symptoms of suspicious character until the third day of illness. (Report Louisiana State Board of Health, 1898–99, p. 74.)

1899—Steamer *Sardinia*, from Vera Cruz; developed yellow fever thirty-six hours subsequent to disinfection. (Report Louisiana State Board of Health, 1898–99, p. 74.)

1899—Non-infected British steamer *Lombard*, from Vera Cruz; six and a half days out; just after completion of disinfection was called to see the second engineer; diagnosis of yellow fever; held twelve hours for observation; diagnosis confirmed; vessel remanded to Ship Island Quarantine Station; patient died three days later. (Letter from Dr. Goldthwaite, Quarantine Board of Mobile Bay.)

1900—Non-infected Norwegian steamer *Bodo*, from Bocas del Toro; five days out; cargo, fruit; living quarters and effects disinfected and vessel allowed to proceed to Middle Bay Light, six miles below Mobile, to discharge cargo into lighters; vessel returned to station in forty-eight hours with one case of yellow fever; remanded to Ship Island Quarantine, where two additional cases developed later; no deaths. (Letter from Dr. Goldthwaite, Quarantine Board of Mobile Bay.)

1900—Steamer *Hugin*, Vera Cruz via Tampico; three and one-half days out; arrived at Mississippi River Quarantine Station June 25; disinfected same day; inspection preliminary to release of vessel on morning of 30th revealed case fever; was taken ill evening previous, four and one-half days after disinfection; case sent to Lazaretto; recovered. (Records, Mississippi River Quarantine Station, 1900.)

1900—Steamer *Electrician*, Belize, via Colon, Vera Cruz and Tampico; three days out from Belize; arrived at Mississippi River Quarantine Station October 7; disinfected same day; on the 8th three cases of fever developed; on the 11th three cases, and on 12th one case, seven in all; cases were all well marked, but all recovered; a convalescent second-class passenger taken on board at Colon was the probable cause of infection. This vessel may be considered an infected vessel and may not be counted. (Records, Mississippi River Quarantine Station, 1900.)

Kahler's Disease.—E. Donetti reports a case of this disease, which is so rare that only sixteen cases of it have so far been reported. The chief symptoms are emaciation, weakness, grave anæmia, pains, softening, fracture of the bones, and deformities. Heteroalbumose is found in the urine, sometimes preceding and sometimes following the period of pain and deformity. At autopsy the ribs, sternum, and bodies of the vertebræ have been found to be affected by a sarcoma-like new growth, which first destroys the marrow and then invades the bone tissue. Lesions of kidneys, liver, and spleen have been found. It is evident that, the bone marrow being unable to continue its functions, a special substance, albumose, is formed, which circulating in the blood causes a true intoxication.—*Rivista Critica di Clinica Medica.*

Catheterization of the Ureters in Renal Tuberculosis.—J. E. Hagen-Thorn concludes that: (1) Tuberculosis of the kidneys occurs more frequently than is generally believed. (2) It is often overlooked, for the first signs of the disease—the appearance of cloudy urine and disordered micturition—are mistaken for cystitis, or, if there is pain in the region of the kidneys, for pyelitis. (3) The appearance of blood in the urine, together with other symptoms, is a pathognomonic sign, though not a certain one. (4) The same may be said of palpation of the affected kidney. (5) Very frequently tubercle bacilli are not found in the urine of the bladder, and the urine seems to be free from microorganisms. (6) According to Israel, Albarron, Koenig, Tuffier, and others, primary tuberculosis of the kidneys occurs not infrequently, and very often only one kidney is affected. (7) The removal of the affected kidney is an eminently justifiable operation. (8) In view of the possibility of both kidneys being affected simultaneously, it is necessary before the operation to ascertain the functional activity of the other kidney. (9) To do this with exactitude, it is necessary, in any mode of procedure, to get the urine from each kidney separately. (10) Of all the methods of getting the urine from each kidney separately, catheterization of the ureters alone achieves this end. (11) Catheterization of the ureters is used for diagnostic, as well as for curative, purposes; it enables the physician to make a diagnosis when the disease of another organ conceals the affection of the kidneys, and *vice versa*. (12) By means of catheterization of the ureters it becomes possible, in doubtful cases, to ascertain the character of the renal affection. (13) It has been used with success in cases in which it was necessary to prevent wounding the ureter. (14) For curative purposes, it has been used in cases of retention of urine within the pelvis of the kidney, for removal of occlusions of the ureter by renal calculi, during operations on the ureter, in the first stages of pyelitis for the purpose of washing out the pelvis of the kidney, for the cure of renal fistulæ by means of prolonged drainage with the urethral catheter.

Bacteria in the Nose.—S. Iglauer finds that the weight of evidence is strongly to the effect that the normal nasal mucus contains bacteria. However, the flora of the nose cannot be as abundant as would be supposed from the number of bacteria inspired; for the following reasons: 1. The surface over which the bacteria are scattered is rather large, about 154 sq. cm. in the nose, and 25 sq. cm. in the nasopharynx. 2. A certain number of bacteria must reach the nasopharynx, from which they are swallowed and digested. 3. The flow of mucus and serum together with gravity tends to carry away the germs. 4. The nasal mucus is not a good culture medium. 5. And most important: The organisms which have lodged in the nose are expelled by the ciliated epithelium with great rapidity. This action has been measured in the frog as at the rate of one inch per minute. 6. A recent work seems to show that the nasal epithelium has bactericidal power. The practical conclusions to be drawn are: 1. It is advisable to sterilize the vestibule of the nose before operating. 2. After operations, the nostril on the operated side should be closed with a piece of cotton to act as a filter. 3. Plugging of the nasal cavity after operations is, as a rule, inadvisable, as it tends to retain the nasal secretions. 4. Nasal wounds do not heal by first intention, owing to the presence of bacteria. This also explains the occurrence of secondary hemorrhage. 5. Fever after operations and the few deaths recorded have probably been due to the presence of pathogenic microorganisms in the nose.—*The Laryngoscope.*

Vocal Nodules.—Commenting on the fact that anatomists have found that the thyro-arytenoid muscle distributes to the margin of the vocal cords fibers which act in a manner analogous to that of the stop-finger on a violin string, limiting vibration to one portion of the cord, C. H. Knight asks if it is not conceivable that contraction of certain bundles of these fibers with too much vigor or excessive frequency may lead to hyperæmia, tissue building, hyperplasia at their point of attachment on the surface of the band. Or possibly a minute localized hemorrhage may take place, and subsequently undergo organization. It would seem reasonable to suppose that the constant tugging upon these fibers in the production of a certain tone might induce an effort of nature to fortify the region of their insertion by throwing out new tissue, or that an effusion of blood might follow a rupture due to sudden and violent muscular contraction. The idea that attrition of the vocal bands might be held accountable as an exciting cause has always seemed to the author untenable for the reason that during phonation space must remain between the bands, in order to permit the blast of air to escape, and hence there can be no friction. Moreover, the node often has its origin, as in a case of Knight's, not on the margin, but on the upper surface of the band.—*The Laryngoscope.*

The Effect of Alcohol on Digestion.—J. A. Storck concludes from his experimental studies that small quantities of alcohol favor salivary and gastric digestion; large quantities inhibit salivary, gastric, and pancreatic digestion. Alcohol, whiskey, gin, and brandy are less harmful to the digestive processes than are malt liquors and wines. The continuous use of alcohol, even in small amounts, is liable to prove detrimental to the digestive process. In persons of weak digestion, alcohol, as a rule, is harmful, unless given well diluted. Strong alcoholics should never be given when the stomach is free of food. Alcohol is a valuable food in disease; requiring no primary assimilation, it yields force rapidly to an exhausted system, and, in small quantities, it promotes appetite. It is well to bear in mind that the purer the whiskey or the brandy, the less liable it is to produce digestive disturbances. According to Dujardin-Beaumetz, the toxic effects of the alcohols increase with the sum of their atomic weights, with the exception of the highest and the lowest. Finally, it is true as Wood says that: "Science in no way contradicts the experience of every *bon vivant* that the small doses of alcohol increase, and larger amounts interfere, with the activity of digestion."—*New Orleans Medical and Surgical Journal.*

Use of Creosote in Pneumonia.—I. L. Van Zandt highly commends the use of creosote carbonate. From his own experience, extending through seven years, he concludes that with it a large percentage of pneumonic cases are cut short or aborted, almost all the rest are mitigated, and the remainder, a very small number, are not at all affected by the remedy. The author prefers the carbonate as the most agreeable form in which to give the remedy. It is almost devoid of taste and odor, and may be given in an emulsion or stirred in hot sweetened water to be taken during agitation, as it does not dissolve. It should not be combined with alcohol or acids, as there will develop the taste and odor of creosote. To an adult seven and a half minims may be given every three hours.—*Southern Practitioner.*

Paralysis in Infants Due to Syphilitic Disease of the Spinal Cord.—The investigations of Jürgens, Zappert, Gilles de la Tourette, P. A. Peters, and others, as well as his own observations, have convinced A. M. Levin that paralysis of the extremities in the new-born and in infants affected with hereditary syphilis is a true paralysis due to disease of the spinal cord, and not a pseudo-paralysis due to local affection of the corresponding muscles or bones. The most characteristic, though not pathognomonic, sign of this disease, according to Peters, is the so-called floating position of the hand. There is great pronation of the fore-arm and the wrist, the palm being turned outward and backward.—*Medizinskoe Obozrenie.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, December 28, 1901.

THE MEDICINE AND SURGERY OF 1901.

THE year that has gone by has not been conspicuous for any especially great events in the fields of medicine, surgery, or hygiene. Much progress, however, has been made in the elaboration and perfection of detail, and in proving the stability of old principles and paving the way for new ones.

The confirmation of the theory, first suggested by Finlay of Havana, that the mosquito stegomyia fasciata is the principal, if not the sole, agency by which yellow fever is conveyed to man, was the most satisfactory work done. Major Reed and the other members of the Army Commission, who came to these conclusions after long and painstaking research, are to be congratulated upon the result of their labors.

The investigations of this commission, however, were made in 1900, and the results were chiefly published in that year; but as a full account of the proceedings was not issued until the meeting of the Pan-American Medical Congress in Havana, in February, 1901, it may be said that the verification of the theory in all its details was made public during the past year. The matter has been dealt with at length by Dr. Finlay and Major Reed in the MEDICAL RECORD as well as in its editorial columns.

The next most important occurrence in medicine in 1901 was the Congress on Tuberculosis in London, in July. The announcement by Koch was one of the most sensational of its kind which has ever taken place at a medical meeting, and the excitement occasioned by the eminent German's attitude has not yet subsided. Its unexpectedness staggered physicians and sanitarians everywhere, but reflection has convinced many of them that the question as to whether bovine and human tuberculoses are intercommunicable will now be probably decided once and for all; and that thus from what at first seemed to be an ill-judged expression of opinion, nothing but good may come.

Of all the diseases which affect the human race, none promise to exceed in interest that of cancer; its increase, its loathsome and deadly nature, and the careful researches at present being conducted with regard to its origin, combine to invest this malady with a surpassing importance. Slight progress has been made during the year 1901 toward the solution of the problem of its causation, and although the investigations of Drs. Harvey R. Gaylord and Roswell Park, at the New York State Pathological Laboratory, did not altogether meet the expectations aroused by the preliminary notices, yet their work and that of their colleagues has not been in vain. Their investigations will be continued steadily under more favorable conditions than heretofore, and it is to be hoped that to American scientists will fall the honor of discovering the origin of a disease which has mystified students for generations. This, with other subjects of current interest, has received special attention at the hands of contributors to the MEDICAL RECORD in 1901.

The treatment of this disease has not materially advanced beyond the employment of the usually recognized surgical procedures of early and radical extirpation. There has been some favorable experience in the use of the *x*-ray, but unfortunately the latter has a very restrictive range of usefulness in consequence of its many liabilities to produce deep necrosis of tissue from the present inability to fix its degrees of relative dosage. Much is yet to be learned in the latter direction, and for the present everything must be left in a purely empirical way to the judgment and experience of the operator. The reason for these lesions is not satisfactorily understood, as yet. The change is evidently not only a chemical one, due to a peculiar action of the rays on the tissues, but also to the extreme vibration and penetrability of the ultra violet or actinic region of the spectrum.

The plague continues its ravages in many parts of the world, its scope has even extended, but unfortunately no remedies of a therapeutic or antitoxic character would appear to exert much influence in checking its spread. The only efficient method of successfully fighting this pest is by proper sanitation.

In San Francisco, the malady, although not entirely extinct, is at a standstill. The proposal utterly to destroy Chinatown has much to be urged in its favor from a strictly hygienic standpoint.

Spinal anæsthesia, according to Corning's method, has had wide recognition by different operators in America and Europe, and by the large number of reported successful cases has seemingly established its claim as a valuable surgical procedure in a certain class of cases in which it would be inadvisable to resort to ether or chloroform.

Public health has always occupied a proper consideration in the columns of the MEDICAL RECORD. The fact is well appreciated that for a community to be healthy—and especially in large cities—strictest regard should be had to matters sanitary. The argument has been advanced by Dr. Knopf and others that tuberculosis might be almost wholly banished if the dwellings of the poor were constructed upon sound sanitary principles. The same writer has contended—with which opinion this journal agrees—that it is the duty of municipal authorities to insist that the houses of the poorer citizens are healthy, and further, that it is for the State to provide sanatoriums for indigent consumptives, and for those suffering from incipient tuberculosis who are unable to pay for such care.

The treatment of appendicitis is a subject that will seemingly not wear out, at least not for some time to come. There is no doubting the fact, however, that so far the surgeons have altogether the best of the argument in favor of early operation, and to all appearances are likely to hold their own in the controversy. The discussion of the question has occupied many columns of the MEDICAL RECORD during the past year, and there has been no lack of warmth on either side.

Much attention has also been given to the operative

measures for prostatic disease, and the papers on that subject during the past year are of the utmost value to the earnest student who is seeking for the best methods of managing that intractable and distressful ailment. The antitoxin treatment for diphtheria still holds its own, although the serum-treatment in other diseases has utterly failed to fulfill the promises of its various advocates.

The new interest manifested in the pathology and treatment of pneumonia is one of the most hopeful signs of the times, and will certainly tend to give the general practitioner new confidence in his expansive therapeutic resources.

So far, however, surgery has not offered any suggestion to medicine regarding improved methods of treatment for this common malady. Not so, however, with Bright's disease, which, according to Edebohls, may now be cured by the knife, and new hope be given to otherwise doomed sufferers.

THE STATE OF THE BLOOD IN CASES OF APPENDICITIS.

THERE has been not a little discussion as to the changes that take place in the blood in connection with attacks of appendicitis, and it cannot be said that there is, as yet, universal agreement upon this subject. It certainly would be a great advance to be able to determine from the condition of the blood the type of appendicular inflammation present, and the stage to which it has progressed. A position of such diagnostic security is to be gained only from persistent and painstaking investigation by many observers.

A valuable and important contribution to this department of knowledge has recently been made by Dr. John C. Da Costa, Jr. (*American Journal of the Medical Sciences*, November, 1901, p. 645), who reports the results of examination of the blood in 118 cases of appendicitis operated upon at the German Hospital of Philadelphia in the service of Dr. John B. Deaver. As a result of this study, it was found that the average case of appendicitis presents before operation a loss of about 30 per cent. of hæmoglobin and of more than half a million of erythrocytes in the cubic millimeter. Occasionally the anæmia is of a grade so high that it appears to constitute in itself a serious complication and to raise a doubt as to the safety of surgical interference, should the latter otherwise be indicated.

Moderate leukocytosis may occur both in the absence and in the presence of an abscess and its consequences. It is present in about 35 per cent. of non-purulent and 90 per cent. of purulent cases. Leukocyte counts ranging between 10,000 and 15,000 or 17,000 in the cubic millimeter cannot be depended upon to reflect the nature of the local lesion, as this degree of increase may be found both in mild catarrhal and in purulent cases. Counts of 20,000 or more are almost invariably indicative of the presence of pus, gangrene, or general peritonitis, one or all. Leukocytosis may be absent both in trivial catarrhal and in fulminant cases, as well as in forms of circumscribed abscess.

In operative cases, thorough evacuation of the abscess is followed within a few days by a decline to normal in the number of leukocytes, provided that the recovery of the patient is uneventful. Persistence of a leukocytosis after the third or the fourth day following the operation may be attributed either to undrained pus pockets, to general peritonitis, or to both of these factors.

From all of the evidence, it is clear that the range of the leukocytes, if correlated with other clinical symptoms, may serve as a diagnostic sign of definite value. On the other hand, absence of leukocytosis, except in conspicuously septic patients, has no definite significance.

A leukocytosis of 20,000 or more is almost a certain indication of suppuration, while a lower figure cannot be relied upon as a trustworthy sign of the presence of pus, although suppuration may be associated with a much lower degree of leukocytosis. In a patient unmistakably septic, absence of leukocytosis is to be considered a sign of intense infection and of grave prognostic significance. A high leukocytosis in such instances does not necessarily indicate a favorable prognosis, but simply represents an intense infection, coupled with normally active resisting powers on the part of the patient. Absence of leukocytosis in a patient with mild, indefinite symptoms is a clinical sign of no tangible value in so far as it may serve in detecting the presence of pus, as a large abscess, if thoroughly circumscribed, may exist without causing the slightest increase in the number of leukocytes.

In cases treated surgically, the adoption of a daily leukocyte count as a routine procedure during the first week after operation furnishes the surgeon with definite information regarding the progress of the case, as the advent of complications or the failure to secure complete evacuation of pus-foci may be detected by the persistence of or an increase in the leukocytosis. Unfortunately, it is just those conditions that bear the greatest resemblance to appendicitis that give rise, as a rule, to blood changes identical with those found in this disease; so that the value of the blood count as a means of differential diagnosis is greatly limited. Thus, leukocytosis is the rule in the presence of such conditions as ovarian abscess, pyosalpinx, ectopic pregnancy, perinephric abscess, hepatic abscess, empyema of the gall-bladder, and malignant disease of the cæcum, all of which have been confused with appendicitis.

Such a large proportion of cases of renal and hepatic colic are associated with inflammatory complications that excite leukocytosis that neither of these conditions can be distinguished with any degree of confidence from appendicitis simply by examination of the blood. Acute gastritis is sometimes accompanied by well-marked leukocytosis and sometimes by none at all, so that the blood count cannot be relied upon in the differential diagnosis from appendicitis. The same statement is applicable also to dysmenorrhœa, the uterine inflammatory changes attending which may cause an increase in the number of leukocytes. Should the diagnosis lie between appendicitis and enteric fever, the former will be suggested by the presence of leukocytosis, which does not occur in the course of typhoid fever, except as a result of some complication such as hemorrhage from the bowel or perforation.

In doubtful cases the presence of leukocytosis is sufficient to exclude such non-inflammatory disorders as simple enteralgia, lead colic, ovarian neuralgia, ovarian cyst, and movable kidney

A plea is made for the more frequent examination

of the blood, not only for the light that it throws upon the coexistent anæmia present in some cases, but also for the purpose of differentiating with certainty a purulent from a nonpurulent appendicular lesion in a fairly large percentage of cases. There is, besides, a limited number of non-inflammatory conditions from which appendicitis may be distinguished by the number of leukocytes. The blood count in cases of appendicitis is to be regarded only as a symptom, invariably to be correlated with other equally if not more important clinical manifestations, and thus used, it will prove of signal value in routine clinical surgery.

THE PAST AND FUTURE OF THE MEDICAL RECORD.

THE completion of the sixtieth volume of the MEDICAL RECORD, with its present issue, is in many respects a subject for congratulation, as during a period of thirty-five years it has maintained a continuous course of prosperity, still holding the premium amongst medical journals in the confidence and support of the profession.

In the first number published, March 1, 1866, the following announcement was made:

"The current medical topics of the day will be freely and independently discussed, and no effort on our part will be spared to render ourselves well informed with reference to them, in order that we may be able to present such views to the profession as shall be considered worthy of its serious attention. In all this our simple aim shall be after truth. Impartial to all and unjust to none, it is our purpose, so far as we are able to understand the right, not to hesitate, on the one hand, to point out the way which, by the correction of certain abuses, may lead to a still higher development of professional excellence; nor to be backward in upholding the claims and discussing the merits of the various vexed questions which are ever arising to claim attention. Committed to the interests of the profession as a whole, it shall be our constant endeavor to keep the columns of the MEDICAL RECORD free from any element that may savor of cliqueism or party spirit, and in the discussion of all subjects, great and small, to exercise that spirit of charity and honesty which must always attach itself to the side of truth and commend itself to the sanction of every independent thinker."

In the same prospectus it is also stated that "The news of the day will be given as completely as our means for receiving information from the different medical centers will allow; and in managing this department no opportunity will be lost for affording full reports upon all matters which are of general interest to the profession."

Since that time many important details have been elaborated in keeping with progressive journalism, but it is interesting to note that the fundamental policy of the MEDICAL RECORD, consistently followed for thirty-five years, is as sound to-day as when the above lines were written.

The MEDICAL RECORD to-day, with special correspondents in every portion of the world, is enabled promptly to inform its readers on all matters of importance from direct sources. The cable and telegraph have largely taken the place of the mail, and frequently even the great dailies are thus anticipated in the publication of interesting scientific news.

In fulfilling its purpose to chronicle its history of progressive medicine, its aim has been to give each branch its due attention, in the hope that no man, whether he be in the most obscure country town or in any of the metropolitan centers, can fail to find in the MEDICAL RECORD something that may interest and instruct him, and make it worth while to read and profit by a professedly cosmopolitan journal.

It may be noted that, no matter how many other journals are taken, the MEDICAL RECORD is one that is always read and preserved as a record of medical progress, and storehouse of practical information. A grand audience, scattered in every portion of the civilized world, relies upon the MEDICAL RECORD for its weekly visits and its satisfying ministrations. All this encourages the MEDICAL RECORD to go on as it began, in the hope that its thousands of readers here and everywhere, and its famous contributors the world over, may still crown with their indorsement its successful efforts to keep advancing with the times, and give it continued opportunities for meriting that cordial support which is so legitimately the reward of demonstrated success.

SMALLPOX IN LONDON.

The epidemic of smallpox in London is assuming very serious proportions, and the advent of cold weather is anticipated with a good deal of dread by its inhabitants. The type of the disease—judging by the mortality therefrom—is much more severe than that of the same affection which has been so prevalent in the United States during the past two or three years. Up to midnight on Friday, November 29, 413 patients suffering from smallpox had been admitted to the wards of the several hospitals under the control of the Asylums' Board of London.

An average it is said of about twenty-five cases of smallpox are being reported daily in London, most of which come from the poorer districts.

The statistics thus far afford further remarkable evidence of the efficacy of vaccination, both in checking the disease, and in diminishing its virulence.

MR. JONATHAN HUTCHINSON AND LEPROSY.

The London *Hospital*, December 7, announces that Mr. Jonathan Hutchinson is about to proceed to South Africa in order to study leprosy, a malady which is prevalent in certain parts of that country. Mr. Hutchinson has always paid much attention to leprosy, and has views concerning the causation of which, more or less peculiar to himself and a small band of followers.

The well-known British dermatologist is, and has been for long, a consistent upholder of the theory that the primary origin of leprosy is due to the eating of uncooked fish. This belief has been in existence for a considerable period, and the geographical distribution of the disease gives a large amount of weight to the theory.

Hansen's discovery, however, of the bacillus of leprosy, was a severe blow to those who held the view that it originated from eating uncooked fish. Nevertheless, Mr. Hutchinson was in no wise discouraged, and is as strong an advocate of these opinions as he ever was, and stoutly contends that race and climate have nothing whatever to do with the incidence of leprosy. It may be anticipated that the results of Mr. Hutchinson's investigations in South Africa will tend to elucidate some of the disputed points as regards the origin of leprosy.

THE MORTON CURRENT.

In view of the fact that so much, both of a general scientific and of a controversial nature, has been published in the Medical Record on this subject, we note with interest the final authoritative and judicial statement made by a special "Committee on the Static Induced Current," appointed by the American Electrotherapeutic Association, September 27, 1900, and adopted by a unanimous vote of the association at its recent annual meeting. The committee consisted of William J. Herdman, M.D., Professor in the University of Michigan, Ann Arbor, and of William J. Jenks, member of the American Institute of Electrical Engineers.

The question of priority raised was not one between contemporary practitioners, but one claimed to lie between Dr. Morton and the printed records of experimenters and physicians not now living.

The committee consulted exhaustively the literature upon the subject and analyzed carefully the methods of Cavallo, Wilkinson, Mauduyt, Duchenne, and others, claimed to be in conflict with the method of Dr. Morton. It sums up the latter's claims to consist in (1) The first intermittent and graduated flow from a static machine, in which the pulses are so frequent that their aggregate may be classed as a current. (2) The first apparatus to make effective a static machine having the advantages of very high frequency and oscillatory or alternating characteristics, without the disadvantages of subjecting the patient to the direct action of the primary or interrupted current. It is then pointed out by carefully constructed diagrams that Dr. Morton's method is essentially different and constituted a new form of undulatory or oscillatory current.

The committee next takes up and analyzes a series of letters published in the Medical Record in its issues of December 23, 1899, and January 20 and March 3, 1900, questioning the novelty of Dr. Morton's claims, and in this respect says, "the committee expresses their belief that if the author of the above-quoted emphatic assertions would review the above prior publications in the light of the diagrams already given in this report, the errors of his observation, which led to his erroneous assertions, would be plain."

The report quotes extensively the opinions of many foreign observers crediting Dr. Morton with the introduction of this form of current into medical practice in 1880, and indicating their opinion also, that the high frequency currents which Hertz secured and described several years later were developed by Dr. Morton and medically applied in 1880. The committee considers the fact has no force that Dr. Morton did not, at the time of his discovery or invention of the static induced arrangement and method, fully appreciate the nature of the electric pulses which he secured, or all the accompanying phenomena, or foresee all of their features of utility, for it is rare that the originator of a machine or combination sees the end from the beginning of its use. It is sufficient that the devices and methods be clearly described, in the best form and mode of application which the experimenter may have worked out (so that others, skilled in the same art, may follow him), to entitle him to the credit of their discovery and reduction to practice, and to a claim to the foundation on which others may subsequently build structures of which he has or may have no conception. The conclusions presented in this exhaustive report are as follows:

"The evidence before your committee indicates that in 1880 or thereabouts, Dr. William J. Morton devised and used an arrangement of previously existing static electrical apparatus, and in its use practised a method of producing currents which have been widely adopted and recognized as useful in subsequent medical work; that the arrangement and method had not theretofore been known or practised, and were not evident to those skilled in the art as a result of their prior knowledge and experience; and that the claims of priority we have detailed as being made by him are entitled to recognition by this association." We congratulate our fellow townsman upon the handsome and thoroughgoing recognition and vindication embodied in the conclusions of this report, and upon the general recognition which is now accorded to him of being the originator of the high-potential, high-frequency current, and of its introduction into medical practice.

The Bland Diet.

The so-called "bland diet" has been the subject of discussion recently, says the *Sanitarian*, December, in the European press. According to the Hanover *Courier*, physicians generally understand by a "bland diet" food that is free from the ingredients which excite heat, but contains or can contain all the nutrients—albumen, carbohydrates, and fat—necessary for the maintenance of man. Wholly different districts of the nervous system are affected by stimulation and excitement.

The usual effect of the substances in which these properties reside is quicker and stronger activity of the heart, accompanied by a sense of palpitation, heat, and so-called ebullition.

Sometimes the effect is a series of acute phenomena, such as headache, etc. When such stimulating and exciting substances are considered, we think naturally of alcoholic beverages, also of coffee, tea, sharp spices, and the like; but food does not always receive all its exciting and healing ingredients in the course of preparation in the kitchen. In many victuals these ingredients are already present, as the result of the origin, manipulation, storage, etc., of the food.

Chief consideration must be here given to meat, in consequence of the amount of extractive substances.

The writer of the article then proceeds to consider meat which has been kept sufficiently long for ptomains to appear, which have a keen and exciting effect.

A "bland diet," one that does not excite, must contain nothing or very little of this. It is common knowledge that milk affords such a nutrient, and passes therefore, justly enough, as the true type of "bland diet." Whoever seeks to spare his nerves should drink milk, and be in all respects a vegetarian. Fat, however, when untainted and fresh is recommended, as are the various kinds of sugar.

The writer does not always advise the avoidance of all foods and drinks of an exciting nature, but a bland mode of living altogether.

The adjective bland, which we take to mean soft or smooth—when used to characterize quality—would imply an easily digested, sustaining, and fattening diet, but one lacking in invigorating properties. Such a diet would probably produce healthy persons, although it would be wanting in those qualities which give one resistance to strain.

It is true that too much meat is eaten and too much alcohol is imbibed by the ordinary individual, but entirely to discard meat as an article of diet, in

the opinion of the majority of scientists, would not be in the interests of health.

Vegetarianism does not suit every one, and each person, if he be wise, will learn by experience what he should eat and what he should drink.

The Determination of Genius.

Professor Cesare Lombroso, who is perhaps the greatest living anthropologist, albeit he holds some peculiar views, and is inclined to be at times too emphatically dogmatic, has been recently writing in the *Monist* on the above subject.

In a former article, he had illustrated, according to his ideas, the nature of genius, and now supplements this by explaining the existence of its varieties. He says: "There is another factor of utmost importance, to which belongs the principal part in this determination, and with which heredity, environment, and the peculiar nature of genius are co-operators; that is, according to my opinion, a strong impression received at puberty. He who analyzes biographies of great men will find that in most cases the determining cause of creative direction lies in the combination of individual tendencies with a very strong sensorial impression made at a time not far from puberty."

After giving a number of instances in support of this theory, he goes on to say: "The great essential in these instances is that they all belong to childhood or pubescence. Now, men are undergoing external influences and strong sensations at any time, but without such reaction as they show at puberty. Puberty has a tremendous importance for one's mental development, on account of its greatest impressionability to external causes. Youth is then in a condition of latent explosibility, ready to burst out under the pressure of every influence, whether of scientific theories or of artistic enthusiasm, or of misfortune, or of strife."

This may be all true, and undoubtedly the age of puberty has a remarkable effect on the development of one's mind. To steer over the quicksands of this period successfully is no easy task for any person, and doubly difficult for a person who possesses those qualities of brain and mind termed genius, but it would seem as if the Professor has somewhat overestimated the force of influence received at puberty, and fails clearly to explain those very numerous examples in which genius has received decisive impulse at an earlier or a later age.

Native Troops for our Colonial Possessions.

Major Louis Livingston Seaman, Medical Department, U. S. A., who has become well known by his fearless championship of the Maligned Army Canteen, and by his views on "The Soldier's Tropical Ration," contributes to the *Journal of the Association of Military Surgeons* a strong plea for native troops for our colonial possessions.

This is a matter which will certainly call for the earnest attention of our government in the early future. If the Philippines are retained—as at least one or two of the islands will be—a somewhat large force must be maintained there for a considerable period. The conditions of life are not favorable to white men, and the expense of keeping up an army wholly composed of Americans would be very large.

Major Seaman points to the policy of Great Britain, in drilling and maintaining armies of natives for the defense of her tropical territories, as an example of what can be accomplished by such means.

Major Seaman appears to have been much impressed by the manner in which the British in Hong-Kong and Wei-Hai-Wei had availed themselves of the native material, and the success which had attended their efforts to convert the Chinese into soldiers. There is no doubt that, when officered by white men, the yellow and black races make capital fighters. The conduct of our black troops at San Juan Hill is but one of many instances in proof.

The cost of the Chinese troops to the British Government for pay and subsistence is $5.00 a month.

Spain, when owner of the Philippines, relied to a large extent upon her native Filipino troops, of whom she had about five thousand. Major Seaman insists that this urgent military question must be met and solved by the United States, and suggests that in the Philippines the material is ready at hand.

War Surgery, Old and New.

One of the last important public utterances of the recently deceased Sir William MacCormac was a paper on the above subject, which he read before the British Medical Association last summer.

No one was better qualified than the great surgeon to speak with authority on the matter, for his experience of military surgery was wide and unique. He acted in his professional capacity through the Franco-German War, saw service during a part of the Russo-Turkish campaign, and as is well known did good work with the British Army in South Africa.

Sir William MacCormac in the course of his remarks said that he would seek to indicate in a general way some of the improved conditions of modern warfare as exemplified in South Africa.

The limited amount of local damage produced in most instances by the comparatively small and very swift Lee, Metford, and Mauser bullets have impressed all observers. The normal external wound is circular and quite small, like the end of an ordinary pencil, and it soon becomes sealed with a black scab of dried blood. The exit wound is often quite similar, or like a small slit, and closes the same way. The soft parts and bone are damaged as a rule in a limited degree, and recovery generally took place rapidly and without complications.

The bullet seems to be itself aseptic; clothing is very seldom carried in with it; the bullet track behaves more like an incised wound than a contused one; the rapid manner in which the small external wounds seal up reduces the injury to the subcutaneous form, and the frequency of recovery is proportionately great.

Sir William MacCormac said that he was much impressed with the small number of cases of primary fatal hemorrhage, and the large number of traumatic aneurysms.

Fatal wounds, contrary to general expectation, are less frequently caused by the modern bullet, than by the bullets fired from the older rifles with low velocity.

In the American Civil War one man was killed for every four and one-half wounded, while with the Mauser bullet the proportion of killed to wounded is one to seven and one-half. Only 6 to 7 per cent. of those wounded now die, whereas in the Civil War the percentage was 14½.

The Röntgen rays were of great Service in South Africa; they localize the foreign body when lodged, and determine the extent and direction of a fracture.

A well-deserved meed of praise was given to hospital ships and trains. The Princess Christian train had in June, 1900, made 102 journeys, carried 7,000 patients, and traversed over 30,000 miles.

The conclusions reached by Sir William MacCormac agree in the main with those come to by Dr. Nicolas Senn, and the United States Army Surgeons during the Spanish-American War. Fighting under exist-

ing conditions between civilized countries is much more merciful than ever before.

It is fitting here to add expressions of sympathy to the medical profession of Great Britain for the loss it has sustained by the death of the late President of the Royal College of Surgeons. The esteem in which he was held by scientific and medical men in all parts of the world was sufficiently demonstrated by the honors and decorations bestowed upon him by the rulers and learned societies of many countries. It is said that Sir William MacCormac was the possessor of more of these testimonials to his ability as a surgeon than any other British medical man. In addition to his preëminent surgical knowledge and skill, Sir William MacCormac was cherished by his many friends for his no less enviable qualities of the heart. His death will leave a gap in the British medical profession which it will be hard to fill.

Domestic Medicine Among the Boers.

The excessive death rate in the concentration camps of South Africa—as was mentioned in the MEDICAL RECORD, December 7—has aroused public attention and indignation in Great Britain. These feelings of anger, however, have been somewhat tempered by the accounts of the manner in which the Boers treat their sick. There has always existed with them a profound distrust of doctors. The Boer preferred to drench himself with all kinds of patent medicines and domestic remedies, and only applied to a medical man as a last resource.

The British doctors in the concentration camps of South Africa are unable to fight against the impenetrable ignorance and prejudice of the Boer women, who will insist upon treating their sick children with domestic medicines.

The Hospital, November 23, has an article which describes in detail some of the therapeutic measures used by the Boers.

For instance, children are coated over with arsenical green paint, and are given internally a compound containing ether, opium, tartar emetic, ginger, and other undisclosed ingredients. A girl with renal dropsy was enveloped from her waist downward in horse dung in order to take the swelling from her face. Cooling drinks are administered to children, prepared from goat's dung variously cooked in oil or in water.

Of course, such methods of treatment do not wholly account for the great mortality in the concentration camps, but they certainly must be a factor in increasing the death rate, and add to the difficulties of the medical men in facing the situation.

Young Men of the United States.

Statistics are gathered, and by some eagerly read, concerning almost everything that takes place here below:

Association Men for November has an article by Mr. C. C. Michener, based on figures furnished by Chief Statistician Hunt of the Census Bureau, relating to the life led by young men in this country.

It appears that 66 per cent. of the young men are unmarried, 34 per cent. being married.

"Fifty-five per cent. of the young men live at home, while 45 per cent. are boarding."

"Forty-six per cent. of the young men in cities of 3,000 or over were born in the country or in towns of 3,000 or less. Three out of seven young men in the country and towns of 3,000 or less look forward to living in the city. Of the population in towns of 3,000 or less, one in seven is a young man. Of the population in cities of 25,000 and over, one in four is a young man. Various other data are presented in the article dealing with the religion, habits, and manner of living of these young men, which would not interest readers of medical journals.

The large percentage of unmarried young men is a salient feature of these statistics, and is of import in the consideration of a serious social problem.

Another instructive point in the data is the exodus of young men to large cities. Whether this be for good or evil, it is hard to determine. Unless there is a constant supply of fresh blood in the cities, the inhabitants will fail mentally and physically, but at the same time it is an open question if this rush to towns is not being overdone. In some countries, notably in Great Britain, the vitality of the population is being sapped by the comparatively unhealthy lives led by the majority of its inhabitants who are dwellers in cities. This probably too is the case, to a lesser extent, in all the countries of the civilized world.

Another Indictment of the Corset.

Many physicians have from time to time protested against the use of the modern corset, and have inveighed against the injury to health of women produced thereby.

It has been left to a slightly fanatic French medical man to suggest a remedy so severe that its application would certainly end the use of the corset entirely. Dr. Marechal asserts that out of a hundred young women who wear corsets only thirty retain perfect health, and proposes that the following stringent measures be enacted to prevent the wearing of these enemies to health:

The first article of the law which the doctor is desirous of having passed forbids any woman under thirty to wear a corset of any kind. Any woman offending in this respect to be punished by three months of imprisonment, or if a minor, her parents or guardians to be condemned to pay a fine of from 100 to 1,000 francs.

Article II permits any woman over thirty to wear any corset she may wish.

Article III provides for the most rigorous formalities surrounding the manufacture and sale of corsets. Every one licensed to sell corsets shall be obliged to take the name, address, and age of every buyer, and shall be subject to fine and confiscation of business in case of an illegal sale.

The French doctor is either a faddist or a wag, and of course the measures proposed by him stand no likelihood of becoming law. The Parisian woman, in particular, is much too careful of her appearance to permit the enactment of legislation which might tend to detract from the beauty of her form, however much it might benefit her health.

A Note on the Treatment of Diphtheria.—John M. Swan reports his management of several cases in a home for colored children. At the first appearance of sore throat, in the first case, he made an inoculation and sent the culture to the board of health laboratory. On receiving word that there were diphtheria bacilli, he made cultures from all the other people in the house and found three positive and two doubtful cultures. Antidiphtheritic serum was given in positive cases with symptoms, 2,000 units, while 500 units were given to positive cases without symptoms and to doubtful cases. As soon as the membrane disappeared from the throats of the patients he applied a sixty-grain to the ounce solution of silver nitrate to tonsils and pharynx after an inoculation; twenty-four hours later this was repeated, and the system was continued until a negative culture was obtained. The patients were, of course, isolated, and an epidemic was averted.—*Proceedings of the Philadelphia County Medical Society.*

News of the Week.

The Boer Reconcentrado Camps.—Another blue book was issued by the Colonial Office in London last Saturday containing a detailed return of the deaths of Boers in the concentration camps in South Africa in the months of October and November, and also during the six months from June to November, inclusive. The deaths of whites in the six months numbered 12,441, including 10,113 children. The death rate per 1,000 per annum for the entire mortality in all the camps increased from 109 in June to 338 in October, and sank to 284 in November. The death rate per 1,000 per annum for children in the month of September was 433, in October 572, and in November 469.

Responsibility for the Camp Mortality in the Spanish War.—At a dinner of the Marion County (Ohio) Medical Society last week, Dr. C. A. L. Reed of Cincinnati spoke of the great mortality in the military camps during the late war with Spain, and accused General Brooke of responsibility in the matter. He said that the commander disregarded the directions and warnings of the surgeons, and so caused a great number of unnecessary deaths. He said that, if General Brooke had disobeyed the scouts and led his men into a trap with as many slain as died in Florida, he would have been court-martialed and shot, but he disobeyed his army physicians, and, in spite of the dire consequences of his disobedience and obstinacy, was allowed to go scot free.

The Stillman Hospital at Harvard.—A correspondent of the New York *Times* announces that the new infirmary for Harvard undergraduates, the gift of Mr. James Stillman of this city, will be opened by the end of the year. The building is a four-story structure of brick and limestone, and suggests in style the Georgian period of architecture. Although smaller than the hospitals in large cities, it is as complete and serviceable in every way, a model of the best in hospital architecture. It is to contain about thirty beds—two wards of eight or ten beds each and twelve private rooms. It is hoped that endowments for free beds will follow, and toward this end a beginning has already been made by the class of '68, which has collected about $3,500. On the first floor of the structure are the office, dining room, matrons' and physicians' rooms, bedrooms, the dispensary, sterilizing and bath rooms, all ranged about an entrance hall finished in quartered oak and floored with marble. Two other floors are given over to the various wards and private rooms, and the fourth floor is devoted to quarters for the nurses. The kitchen is in the basement, and there, too, are the dining rooms for the servants, the laundry, and the heating and elevator apparatus.

Immunizing Cattle Against Tuberculosis.—Professor Behring, a recipient of one of the Nobel prizes, in a lecture delivered in Stockholm on December 13, said that he had experimentally demonstrated the possibility of rendering cattle immune from tuberculosis by inoculation. He added that he proposed to employ the Nobel prize money in combating cattle tuberculosis.

Last Summer's Campaign Against Mosquitos in New Jersey.—The mosquito exterminating committee of the South Orange Village Improvement Society issued its first annual report a few days ago. The committee declares that the work done the past summer was a success. The report says that during the past season there was furnished "ample ocular proof that standing water is the source of the local supply of mosquitos; also, that mosquitos and mosquito larvæ are killed by contact with oil. The real remedy is the removal of water itself, and that is merely a question of drainage. It is reasonable to expect that the present universal agitation of this question may bring the general public to the belief, already expressed by scientists, that mosquitos are no more a necessary evil than smallpox or yellow fever."

Indictment Against a Healer.—The Grand Jury, in the United States Court at Jacksonville, has returned a true bill against a "healer" named Helen Post, or Williams, of Sea Breeze, Fla. The indictment charges that the defendant was guilty of fraud in representing that she possessed the power of mental science, or mind cure, to cure disease. The case promises to become celebrated, as the Mental Scientists, at their recent national convention in Sea Breeze, voted to help in the defense of the accused woman and her associates. Mrs. Post was arrested last August, and has been under $5,000 bail. Her husband and her son-in-law were indicted in Macon, Ga., last month.

A Medical Club in Paris.—A medical club has recently been founded in Paris at No. 5 Avenue de l'Opéra, in premises belonging to the Cercle National. Its object is to promote friendly relations among its members, to form a professional center for the medical practitioners of Paris, and to provide the advantage of a club for provincial and foreign doctors visiting Paris. Visitors will be able to obtain at the club all the information they may require as to lectures, hospital visits, scientific and medical societies, etc. Professor Pozzi is the president, and Dr. Doleris the secretary general of the club.—*British Medical Journal.*

Baked Beans and Accident Insurance.—A Philadelphia widow is suing an accident insurance company for $5,000 damages, the amount of an accident policy she held on the life of her late husband. He had been suddenly taken ill with what was supposed to be either typhoid fever or appendicitis, and lay at death's door for several days. Then his condition began to mend, and with the improvement came a strong desire for more substantial food, so he asked his wife to prepare some baked beans, of which he ate a great quantity. Soon afterward he was taken with severe pains and died. The post-mortem examination showed that the beans had perforated the man's intestines. The widow holds that the fatal result may properly be termed an accident. Hence the suit.—*Medical Examiner.*

The Stony Wold Sanatorium.—Several lots of land in Township Ten of the old military tract in Franklin County have been purchased by the Stony Wold Sanatorium as a site for its institution. The project for the establishment of this sanatorium is one in which many people in New York are interested, and has for its object the furnishing of a temporary home for dependent young women who are threatened with pulmonary diseases. The property was purchased from Arthur G. Leonard and Benton Turner of Plattsburg. A nominal consideration only was paid to Mr. Turner, he virtually donating the property owned by him. The tract is about 1,000 acres in extent, and includes the Kushaqua Hotel property, which will possibly be utilized for the present for the sanatorium. It also includes Round Lake, a small body of water well known for its beauty.

The Prospects of Medical Union in New York State.—The New York County Medical Association, in its reply to the recently published resolutions of the Medical Society of the County of New York, concerning a union of the two societies says that the

charter and by-laws of the New York State Medical Association do not allow its county associations to act independently on State questions. It has passed resolutions, however, in favor of a union of the profession in one State medical body, and suggests that the Medical Society of the County of New York request the Medical Society of the State of New York to appoint a committee to consider this question. The association has also requested the New York State Medical Association to appoint a committee of conference in case the Medical Society of the State of New York shall appoint a similar committee.

A Slow Diagnosis of Smallpox.—A man with high temperature and a rash spent three days last week in the Fordham Hospital in a general ward with twenty other patients. For some reason, which the published reports do not give, the nature of the disease was not suspected during this time. As soon as the diagnosis was finally made, the man was removed to North Brothers Island, and such of his fellow patients as still remained in the hospital were vaccinated.

The Late Dr. Thomas M. Markoe.—At the first autumn meeting of the Medical Board of Mount Sinai Hospital a committee of three members was appointed to take action upon the death of Dr. Thomas M. Markoe, and the following resolutions were subsequently adopted by it:

Whereas, Dr. Thomas M. Markoe has been for a period of forty-six years a Consulting Surgeon of Mount Sinai Hospital, and

Whereas, Death has removed him from the profession in which he labored faithfully as a teacher of medical students, and as an adviser of his colleagues; therefore

Be it Resolved, That the Medical Board of Mount Sinai Hospital places upon its minutes this expression of its pride in his long and honorable career, and of sorrow at his loss; and furthermore,

Be it Resolved, That a copy of these resolutions be forwarded to the family of the deceased, and be published in the medical press.

ARPAD G. GERSTER,
HOWARD LILIENTHAL,
ALFRED MEYER,
Committee.

December 14, 1901.

The Declining Birthrate in France.—The statistics just published by the government concerning the population of France in 1900 are less satisfactory than those of the preceding year. In 1899 the excess of births over deaths was 31,394, giving the hope that France was slowly rebuilding its population, but in 1900, there was an excess of 25,988 deaths over births. In only two departments, the excess of births over deaths in 1900 was greater than in 1899. In thirty other departments the number of births in 1900 was greater than that of deaths, but that excess of births was inferior to that of 1899.

A New Intestinal Antiseptic?—A newspaper report from Ann Arbor says that experiments by Dr. Frederick Novy and Prof. Paul C. Freer, a chemist, have produced what is believed to be an efficient antiseptic for such specific diseases with intestinal lesions as cholera, typhoid fever, and dysentery. The preparation has been tried with success in experiments on small animals previously inoculated with these diseases, and in the last week five medical students have been undergoing experiments with the preparation.

The Eastern Medical Society of New York City held its annual meeting December 14. The following officers were elected for the ensuing year: *President*, Dr. A. Abrahams; *First Vice-President*, Dr. Joseph Barsky; *Second Vice-President*, Dr. E. K. Browd; *Secretary*, Dr. Maurice Fishberg; *Treasurer*, Dr. B. Gordon; *Chairman of Ways and Means Committee*, Dr. A. Hymanson; *Chairman of Committee on Ethics*, Dr. A. A. Himovitch; *Trustees*, Drs. A. Brothers and William S. Gottheil.

Tri-State Medical Association of the Carolinas and Virginia.—The fourth annual meeting of this society will be called to order in Asheville, N. C., February 25, 1902. All Fellows intending to read papers are requested to communicate with the secretary, Dr. H. A. Royster, Tucker Building, Raleigh, N. C., giving title, not later than January 15, 1902.

Conference for Union of New York County Societies.—The suggestion of Dr. Frank van Fleet, President of the Medical Society of the County of New York, that committees from the two county medical organizations meet and confer with reference to a union of the two organizations, was very cordially received by the New York County Medical Association, and in response thereto the following preamble and resolutions were unanimously adopted at the stated meeting of the association on December 16:

"Whereas, the following resolution has been received from the Medical Society of the County of New York: 'Resolved, That the President of the Medical Society of the County of New York appoint a committee of five, of which he shall be chairman, provided a similar committee be named by the New York County Medical Association, to confer with that body with reference to a union of the two organizations; and that this committee be requested to report to the society at the stated meeting in January, 1902, or sooner, in order that this society may, if desirable, make a recommendation to the Medical Society of the State of New York at its next annual meeting;' and

"Whereas, the subject of union of the medical profession in this State, as expressed in the foregoing resolution, as presented by the Medical Society of the County of New York, is wholly a State question; and

"Whereas, the published charter and by-laws of the New York State Medical Association do not allow its county associations to act independently on State questions;

Be it Resolved, That we heartily favor a union of the profession in one State medical body, and respectfully suggest that the Medical Society of the County of New York request the Medical Society of the State of New York to appoint a committee to consider this question; and

"Be it further Resolved, That the New York County Medical Association request the New York State Medical Association to appoint a committee of conference in case the Medical Society of the State of New York shall appoint a similar committee."

OGDEN C. LUDLOW, M.D.,
Secretary.

Pathological Society of Philadelphia.—At a stated meeting held December 19, Drs. J. M. Anders and Jos. McFarland exhibited a specimen of "gangrene of the lung," in which the condition had been latent during life. On post-mortem examination, however, almost the entire lower lobe of the lung was found in a gangrenous state. Dr. Jos. McFarland exhibited a specimen of "Diverticulum of the Œsophagus," obtained from the body of a man who during life had been addicted to alcoholic excess, and was supposed to be suffering from carcinoma of the œsophagus. Dr. David Riesman exhibited a specimen of "Bothriocephalus latus," obtained from a Russian, but concerning the source of which no additional information could be gained. Messrs. E. B. Vedder and

C. W. Duval presented a communication upon "The Etiology of Dysentery in the United States," in which they detailed the outcome of an investigation of cases of acute dysentery in various parts of the country, undertaken by means of a grant from the Rockefeller Institute for Research, and as a result of which they found in every instance bacilli, indistinguishable from those described by Shiga, Flexner, and others, as the causative agent of the disease in question. Dr. J. Dutton Steele exhibited specimens from "A Case of Diabetes, in which autopsy showed Chronic Interstitial Pancreatitis with Involvement of the Islands of Langerhans." Dr. Alfred Stengel exhibited a specimen of "Mucoid Cyst of the Vermiform Appendix," known also as mucocele. Dr. M. P. Ravenel exhibited a specimen from "A Case of Tuberculosis of the Skin Due to the Bovine Tubercle Bacillus." The specimen was obtained from a laboratory assistant who was inoculated from a tuberculous cow, and who developed tuberculosis of the skin, in the lesions of which were found tubercle bacilli and giant cells, and with the tissue from which guinea-pigs were successfully inoculated.

Vaccination by Osteopaths Not Recognized.—The School Board at Ashley, Pa., has refused to accept certificates of vaccination performed by osteopaths. Several hundred children are affected by this, and before they can get into school will be required to have a second operation in order to get a certificate from a registered physician.

Consumptives Excluded from Liberty.—The Health Board of Liberty, N. Y., has ordered that no hospital or sanitarium for the reception of consumptives shall be maintained within the village limits, and that tuberculosis shall be classed as an infectious disease, like smallpox and diphtheria, and sufferers from it be reported and quarantined if thought necessary. This is one of the logical results of the intemperate outcry regarding the infectiousness of tuberculosis, another being the ridiculous and cruel, but fortunately in the long run, futile attempt of the immigration authorities to prevent the entrance into this country of any tuberculous subject.

The Pathological Institute.—Dr. Adolf Meyer of the State Hospital and Clark University, Worcester, Mass., has been appointed by the Lunacy Commission to be Director of the Pathological Institute of the New York State hospitals in place of Dr. Ira Van Gieson, who resigned early last summer. Dr. Meyer is a graduate of the University of Zurich in 1890. In 1893, he went to Chicago, where for two years he was pathologist at the Illinois Eastern Hospital for the Insane and lecturer on neurology at the University of Chicago. He was then called to Worcester, Mass., as director of the clinical work and laboratory of the Worcester Insane Hospital. The scientific work of the reorganized institute will be begun as soon as possible in a building connected with the Manhattan State Hospital for the Insane on Ward's Island. The investigation and research will be developed along lines to be formulated by Dr. Meyer in association with the Advisory Board of the Pathological Institute. Dr. Meyer is to be left free to select his assistants in the various departments of the laboratory work, but will be assisted in this selection by the Advisory Board. A salary of $5,000 is attached to the position.

A Centenarian Squaw.—An Indian squaw, Mus-Su-Ga, mother of the Winnebago Chief Red Snake, died near La Crosse, Wis., on Saturday last, at the reputed age of 128 years. She lived most of her life in northern Michigan, but had recently moved to an Indian camp on an island in the Mississippi River opposite La Crosse.

Obituary Notes.—Dr. George Bayles, of Orange, N. J., died suddenly on December 20, at his home in that city, of heart disease. He was born in this city in 1836, and was graduated in arts from the College of the City of New York in 1856, and in medicine from the College of Physicians and Surgeons in 1859. He was at once made curator of the pathological department of the New York Hospital, but soon resigned in order to go abroad to study. At the breaking out of the Civil War he was appointed assistant surgeon in the Twenty-fifth Regiment, New York Volunteers. He was afterward transferred to the First Regiment, New York Heavy Artillery, which later became the Fourth Regiment, and was made a surgeon with the rank of Major. Returning from the war, Dr. Bayles settled at Irvington-on-the-Hudson, and for a time was sanitary inspector for that place, as well as inspector of children's diseases for the New York Board of Health. He became a fellow of the New York Academy of Medicine in 1867. He moved to Orange in 1879. Dr. Bayles had been a member of the staff of the Orange Memorial Hospital for the past thirteen years. He was a member of the Orange Mountain Medical Society, the Essex District Medical Society, and the State Medical Society. With the outbreak of the Spanish War, Dr. Bayles tendered his services to the Government, and they were promptly accepted. He was made Post Surgeon at Fort Hancock, where he organized and equipped the military hospital at that place. At the close of the war he returned to his home in Orange and resumed his practice. A widow and six children survive him.

Dr. John Stark of Kansas City, Mo., died at his home in that city on December 17, of pneumonia. He was a graduate of the Royal University of Glasgow in 1863, and a licentiate of the Faculty of Physicians and Surgeons, Glasgow, the same year. Immediately after graduating, he came to this country and volunteered his services as surgeon in the army, and for two years was on the staff of General McClellan. At the close of the war he went West and entered upon private practice.

Dr. Timothy D. Wadsworth, aged sixty-four years, a retired physician, dropped dead from heart disease on December 17, at Warehouse Point, Conn.

Dr. Vincent Nager of Newark, N. J., died on December 20 at his home in that city. He was born in Switzerland fifty-two years ago, and received his medical education there. He came to this country at the age of thirty years and established himself in Newark. He was a member of the staff of the German Hospital in that city. A widow and three children survive him.

Dr. Rush S. Huidekoper died in Philadelphia on December 17, at the age of forty-seven years. He was born at Meadville, Penn., and was educated at Phillips Academy, Exeter, and at the University of Pennsylvania. He was graduated in medicine at the latter institution in 1877, and immediately proceeded to a study of veterinary surgery. He attended the National Veterinary School, at Alfort, France, and continued his investigations in the laboratories of Pasteur, Virchow, Koch, and Chauveau. Returning to America, he was appointed a professor at the University of Pennsylvania, and later filled the Chair of Internal Pathology and Contagious Diseases at the New York College of Veterinary Surgeons. Dr. Huidekoper was connected with the Medical Corps of the National Guard of Pennsylvania for several years, occupying various positions of importance. He was also Lieutenant-Colonel and Chief Surgeon of the First Army Corps and of the United States troops in Porto Rico.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL COUNCIL—MOVABLE KIDNEY—ALKAPTONURIA—REMOVAL OF GASSERIAN GANGLION—LONDON WATER BILL—SMALLPOX—ROYAL BART'S—DEATH OF SIR W. MACCORMAC.

LONDON, December [illegible], 1901.

THE Medical Council continued its session on Tuesday afternoon. A whole day and a half were occupied with the case of a doctor who is medical officer to a friendly society which was said to tout for patients. The charge was made by the defense union, and it was alleged that a canvass was carried on from door to door, without regard as to whether the patients had advisers or could pay. Of course, the doctor denied that he was aware of any such proceedings, and said, so far as he could find out, there was no canvassing. In the end, the council pronounced the charges to be satisfactorily proved, but adjourned action until next session, to give the doctor an opportunity of reconsidering his position. Unless he wants to be removed from the register, he had better cut all connection with medical aid associations, apologize, and promise to have no more to do with them; for otherwise the council, having pronounced him guilty, can hardly refrain from pronouncing sentence.

Although so long a time was spent on this case, there is a good deal of satisfaction expressed that the matter was fully gone into, as it is hoped that the council will abide firmly by its decision, and that these medical aid associations may be put down.

The revolt of the London colleges was fully discussed, and a resolution taken which may mean much. A committee was appointed to prepare a report on the differences that exist, and a special meeting is to be held to consider such report and decide what action, if any, should be taken. The weak point in this move is that a special meeting will further deplete the funds, and there is really no need of a committee, for every member of the council knows the facts. The council has hardly the courage of its convictions. The disgraceful climb down to the obstetrical society is fresh in every one's remembrance, and the fear is consequently general, that the bluff of the colleges will lead to another retreat.

Sir William Turner was unanimously re-elected president of the council for the next five years.

The report on Italian degrees was adopted. It stated that they showed a sufficient standard for registration.

The report of the education committee on the request of the Society of Anæsthetists to make their subject compulsory in the curriculum was approved. The report said the committee fully appreciated the importance of the subject, but were not prepared to advise its compulsory teaching as a separate subject. This is only reasonable, for all the hospitals teach anæsthesia, and to set up another course would only oppress students with additional fees and worry.

Some electioneering squabbling was introduced and would probably do no good to any candidate. Mr. Housley's vigorous attacks on some of them are hardly worthy of his position.

Movable kidney was discussed at the last meeting of the medical society. The paper was by Mr. Henry Morris, whose name is associated with renal surgery. It was, therefore, refreshing to find that so great an authority is no advocate for a hasty resort to operation. He laid it down explicitly, that when a movable kidney gives rise to no inconvenience, an operation ought not to be thought of, and a belt need not be worn. When the condition is associated with enteroptosis, nephropexy may be resorted to, but not unless it is clear that the serious symptoms are due to the kidney alone, and not until after well-fitting abdominal support and dietetic and medicinal treatment of gastric and intestinal disorders have failed to afford relief. A similar course applies when the liver is also mobile. When both kidneys are movable, Mr. Morris fixes one after the other, leaving only a week's interval, so that convalescence may proceed simultaneously from the two operations. In hysterical patients, all palliatives must be tried before operation, and if undertaken, the friends should previously be told how uncertain is the result, only about half such cases succeeding.

In uncomplicated cases of floating kidney, with pain and gastrointestinal troubles as the principal symptoms, Mr. Morris said operation might be carried out without previous trial of belts or of rest. Further, when renal crises are a feature, nephropexy ought to be recommended because of the impossibility of keeping the kidney in its place by belts, and because of constant risk of hydronephrosis, nephropexy is successful.

It has entirely superseded nephrectomy, and is the only justifiable operation for movable kidney.

Mr. Morgan remarked that rest was of little value. Operation generally relieved the symptoms, but he had known them to recur.

Dr. Maclagan differed as to the value of rest. One of his patients after six weeks' rest continued quite well when seen about a year later, and the kidney was not then movable. Other cases were also successful. He also mentioned cases in which operation was undertaken for gallstone, but no stone found, only a movable kidney which was fixed, and jaundice was cured as well as the attacks of colic.

Mr. Bruce Clarke attributed the cases cured by rest to enteroptosis. The most important point was the degree of pain endured. He thought the pain due to retention of urine in the pelvis of the kidney, and it could sometimes be relieved by squeezing out the fluid by abdominal pressure. The gastric troubles he thought due to the direct traction on the stomach.

Mr. Swinford Edwards said it was important to replace the kidney above the margin of the ribs. He mentioned a case in which the kidney became movable again some time after nephropexy.

Mr. Bidwell had also observed a tendency to return of the symptoms after two or three years.

Mr. Spencer considered the pain often due to slight hydronephrosis, and he had sometimes incised the kidney as well as fixed it.

In reply, Mr. Morris thought the cases cured by rest were probably enteroptosis; deficiency of nephritic fat tended to movable kidney; jaundice he did not think due to pressure on the biliary passages, but perhaps to dragging on the duodenum obstructing the duct at its entrance; increase of size, he thought due to obstruction of veins rather than hydronephrosis; he had never seen hydronephrosis follow operation; Vallieti's operation, he regarded as too severe, though it had the advantage of drawing the kidney up under the ribs.

Mr. Bryant related to the Medico-Chirurgical a case of intestinal obstruction, which on operation was found to be due to pressure of a vesical sacculus. Somewhat similar cases were mentioned by others, but not precisely the same, as adhesions had been found in all. The surprising point in Mr. Bryant's case was that there was no sign of inflammation or adhesion. The intestine was empty below the pressure, but on lifting the obstruction, fæces flowed freely enough.

Dr. A. E. Garrod then read a communication on alkaptonuria, a subject on which he read a paper before the society in 1899. In four families he found alkaptonuria in eleven members; in three of the families the parents were first cousins, in the fourth there was no blood relationship. This is certainly a curious observation when we consider the rarity of the condition, and the small proportion of marriages of cousins. It is not a question of intensification of family peculiarities, for none of the parents were subjects of alkaptonuria—a condition, moreover, which has not been recorded in two generations of a family. One of the cases was an infant; the staining of napkins was not present the first day of life, but was pronounced fifty-two hours after birth and continued constantly, suggesting that the homogentisic acid, to which such urine owes its peculiarity, follows the introduction of food into the alimentary canal, and supporting the view that the acid is produced from tyrosin in the digestion of proteids.

Further, that the homogentisic acid is produced in the tissues, and not in the intestines, as has been sometimes thought.

At the Clinical Society on the 22d inst., Mr. Morse related two cases of intracranial section of the trigeminal for neuralgia, cure resulting in both.

Mr. Hutchinson, Jr., reported five cases in which he had excised the Gasserian ganglion, and exhibited four of the patients. In not one was there any recurrence of the neuralgia. He urged that the temporal route should always be taken to reach the ganglion—this (Krause's) being in every way superior to the pterygoid route (Rose's). He thought the mortality in skilled hands probably under 10 per cent., and so lasting were the results that other operations would be abandoned in favor of the Hartley-Krause. He felt that the victims of epileptiform neuralgia should not be left to develop suicide before having the chance of permanent cure by operation.

Mr. Wallace mentioned a case in which the whole ganglion could not be removed, but the patient recovered and remained free from neuralgia. He did not seem decided as to which operation should be preferred, and had heard that the temporal route was falling in favor in America.

Mr. Ballance had removed the ganglion in ten cases—in one woman of eighty-four and another of seventy-one

cars, and thought old age no bar. He operated in two stages, with four or five days interval, if at one sitting the risk was much greater. He hoped the time would come when it would be possible to separate the sensory from the motor fibers, and divide the former without the latter.

Mr. Wallis mentioned a case in which arrangements had been made for operation, but previously the teeth were once more carefully examined and three stumps removed, which cured the neuralgia.

A paper was afterward read by Mr. Howard on a case of fragilitas ossium, and some other cases were mentioned in the discussion. Some of these were associated with congenital syphilis, but in others there was no trace of this.

Government having intimated that a water bill for London will be one of their chief undertakings for the coming session, the subject is again attracting attention. Whatever the statement may be worth that they are determined to push a bill through, there is sure to be opposition and the monopolies of the companies will find sympathizers in both parties. The County Council will again put in its claim to control the supply and find a new one, and the success which has attended the municipalization of the supplies of other large towns is a strong argument with oppressed rate-payers for permitting London to do likewise, instead of setting up another board elected on a complex plan.

Smallpox is still on the increase—from twenty-eight to thirty-three notifications a day have been made this week.

On Tuesday, the Prince of Wales was duly installed President of St. Bartholomew's Hospital, in succession to the King. So the ancient foundation of old Bart's retains its connection with royalty.

The committee of Macclesfield Infirmary, having forced the staff to resign by appointing in opposition to their wishes a woman house-surgeon, are now asking them to come to a conference.

Sir Wm. MacCormac, Bart., died suddenly on Wednesday. He was Hon. Sergeant-Surgeon to the King, Consulting Surgeon to St. Thomas' Hospital, and was President of the Royal College of Surgeons for the long period of five years. He had also received an unusual number of honors, academical, social, and knightly.

His sudden death came as a surprise to many who had noticed the vigor of his speeches since he returned from South Africa. But they were deceived by his fine presence and energy. Some knew that he contracted dysentery at the Cape, and was not free from its consequences, and with this guide were able to see that with all his energy in public there were signals of diminished vital force to the careful observer.

You will remember that he joined the Anglo-American ambulance in Paris during the Franco-German War, and received honorary distinctions for his services from both combatants. He went also to the Servian War. It was not surprising, therefore, that when our government decided to seek civil surgeons to aid in South Africa, they should turn to one with his experience of military surgery. He was Secretary-General to the International Medical Congress here in 1881, at the close of which year he was knighted. In 1897, while president of the college, he received a baronetcy. The next year he was called to treat the Prince of Wales—now king—for fractured patella, and afterward received the K.C.V.O. This year the K.C.B. has been added in acknowledgment of his services in South Africa.

SOME OBSERVATIONS ON DECAPITATION IN CHINA.

To the Editor of the Medical Record:

Canton, China, November 16, 1901.

Sir: The following points of interest were noted to-day while closely observing the decapitation of thirty-six Chinese criminals in the City of Canton.

The prisoners were all placed in a kneeling position in a double row, and rather close to one another. The arms were tied behind, the queues were twisted into a knot on the head, with a tag on each queue and on the shirt. The men showed no signs of being under the influence of opium.

The sword used was about twenty-seven inches long, four inches wide and was a heavy, two-handed, chopping affair. Two executioners did the work cleanly and rapidly, and in all but three cases the heads fell at a single stroke; in two of the three exceptions the necks were only held by a small skin attachment; in the third case the blow seemed to strike about the sixth cervical vertebra and cut about two-thirds through.

Among the interesting features of the execution I noticed: (1) In many of the cases a decided effort to swallow was shown by the expression of the mouth, and the movement and downward bulging of the throat were repeated two or three times; (2) In several cases there was a pronounced attempt to articulate, judging from the labial expressions and movements. This movement was not convulsive, but most deliberate and expressive; the men were not in the act of speaking when the blow fell; (3) On close examination of the faces at the instant when the head fell, several showed a look of surprise and intelligence; this was, of course, but for a second; a natural movement of the eyes as if looking, and an opening and closing of the lids occurred. (4) There were no convulsive movements in any of the bodies or legs. The bodies fell forward, often covering the heads; (5) Close examination of the facial expression impressed me with the idea that it was the face of a person in syncope; the eyes, eye-lids, lips, color, and general expression were those of a person who was about going into a deep faint. (6) The hemorrhage from the trunk was tremendous; the carotids, during their three to six pulsations, each with diminishing force and volume, threw a stream of blood variously estimated in some cases from two to three feet. There was no spurting from the head.

I was strongly impressed with the idea that death was not instantaneous, but that it came almost immediately after the stroke and in syncope.

Oliver D. Norton, M.D.
Surgeon U. S. Navy.
U. S. S. *Monadnock*.

PROPOSED INCREASE IN THE POWERS OF THE ARMY MEDICAL CORPS.

To the Editor of the Medical Record:

Fort Thomas, Ky., December 11, 1901.

Sir: I request that you will publish the following response to your editorial of November 30, 1901. I thank you for the editorial.

Paragraph 1393, Army Regulation, 1895, to which reference is made, has, as your writer most truly said, wrought great good for army sanitation. This regulation, however, is based upon the results arrived at by the British, when they had an investigation of their army medical department following the Crimean War. The sanitary faults of that investigation the world knows. It was based upon the knowledge of that day. In this day sanitary science has greatly advanced. The world tends toward specialism. The line officer is already a highly specialized man, the purpose of whose education is the destruction of the force opposed to his own. When this purpose is to be attained, every other consideration must be laid aside. For this reason the line must have absolute and unquestioned control of men and material present.

No man can question but that the line officer who would deliberately compel his men to occupy a hospital infected with the contagion of smallpox should be punished for needlessly exposing his men. On the other hand, should this same infected building be the key to a battle position, and he refuse to occupy it on account of the contagion, and lose his battle thereby, all would properly condemn him. It is far better to risk smallpox contagion than to lose the entire command through fear of the disease. Therefore, the line must always retain the right to encounter sanitary dangers, just as other dangers must be encountered, for they may be but a small percentage of the totality to be faced. Whenever men are given power to control, they must do so with the responsibility resting upon them that the judgment used was accurate, and they must be made to feel that there is a penalty to be paid when men's lives are lost from a misapplication of the powers with which the Government must, per force, intrust them.

Your writer does me injustice when he attributes to me the opinion that commanding officers, as a rule, pay no attention to the recommendations of the medical officers. All the better men do pay attention, do try to have the recommendations carried out. One meets with all classes of men, from bitter oppositionists to active, earnest assistants.

My contention is and was that the duties of the Army Medical Department should be defined by statute law, and not left to be controlled solely by regulations. Regulation is only another name for the orders of the Secretary of War that the responsibilities be fixed by law, so that, when unusual losses occur from disease, some one man, who under the law is responsible, may be punished by due legal process. No line officer, knowing that if he countermands the recommendations of the medical officer, he thereby renders himself liable for results, will hesitate for a moment to compel the medical officer to enforce the sanitary law as the medical officer thought was for the best interests of his command, for then the

medical officer remains responsible for the result. On the other hand, when the enemy is at hand, the line will at once treat sanitary dangers on precisely the same footing as any other danger is handled. To defeat the enemy should be the sole aim—with small cost, if possible, but at any cost that may be necessary.

It is a difficult matter so to draw a law that it will apply to each and every case, and if your writer can compose such a law, he should announce it to all and undertake for the general good to have it become law. Certain it is that such a law is greatly needed.

The bill which was introduced by the Hon. Jas. Hay is the only attempt of which I have knowledge to fix the responsibilities and penalties.

The regulation which your writer proposes does not require the action of the Secretary of War; it is entirely within the province of any commanding officer to order it for himself and his command.

I quote from your editorial: "Something may certainly be done toward the improvement of sanitary conditions, but not in the manner or to the extent proposed by Major Owen. Under no circumstances will military conditions tolerate any division of the powers of the commanding officer; and, so far as he himself is concerned, the recommendations of his surgeon must be advisory." Continuously throughout my paper will be found the thought that no commanding officer can afford any division of his authority, for this must be absolute and unquestioned. There can be no reason, however, why a commanding officer may not be held to a legal responsibility for his actions, nor can there be good reason why he may not act under statutory law rather than regulation.

Sanitation is a study which embraces almost every science. Its laws are delicate and difficult of application, and it is my belief that too many of these laws are now known to allow the application of that which is known to depend upon the haphazard of regulation. We should have at least a statute upon which to base the regulation. Demand good results, and punish failure to obtain them. Fix the responsibility on some one man, give him power to enforce his orders, with penalties for failure to obtain results, and you will have the same results that obtain in civil life.

Very truly,

W. O. Owen, M.D.,
Major and Surgeon, U. S. Army.

Curable Bulbar Encephalitis.—According to B. A. Muratoff all acute inflammations of the nervous system may be divided into three forms—hemorrhagic, interstitial, and parenchymatous. The last two forms he considers curable. He defines encephalitis as a parainfectious form of inflammation, *i. e.* a malady occurring in connection with various infectious diseases. Encephalitis thus presents the following clinical characteristics: (1) It may be due to a past acute infection; (2) It may occur independently of any previous infection; (3) It may occur in the absence of any specific microorganism and the corresponding specific symptoms; (4) It may be due, not to the direct action of the microorganisms, but to that of their toxins.—*Meditsinskoe Obozrenie.*

The Influence of Various Metals on the Morphological Composition of the Blood and the Formation of Hæmoglobin.—M. A. Iliasheff arrives at the following conclusions: (1) Copper, mercury, and manganese salts introduced in small quantities per os produce no perceptible influence on the number of the red blood corpuscles; (2) The iron salts under the same conditions always produce an increase in the number of the red blood corpuscles; (3) Not only are the iron salts thus absorbed and produce a stimulating influence on the blood-producing organs, but they are also assimilated and go to build up the components of hæmoglobin; (4) The increase in the number of the red blood corpuscles and the amount of hæmoglobin occurs in such a manner that first the maximum of the number of the red blood corpuscles is reached, while the maximum of the amount of hæmoglobin appears later; (5) With the use of iron the percentage of the eosinophile cells of the blood is always raised; this does not occur under any other conditions in the same animals; (6) The eosinophile granules contain iron, and apparently in stable organic combination, since, like the hæmatogen of Bunge, they give the reaction of iron with ammonium sulphate only after from twelve to twenty-four hours.—*Vratch.*

Progress of Medical Science.

Boston Medical and Surgical Journal, December 19, 1901.

Acute Intestinal Obstruction Occurring Twice in the Same Subject.—Homer Gage reports the case of a man seventy-five years old on whom another surgeon had operated for cancerous stricture of the intestine in the lower half of the sigmoid flexure, resecting about six inches of intestine, and making a careful end-to-end anastomosis with suture. Five years later another operation was done for constriction due to a coil of small intestine on the left side just below the umbilicus being tightly constricted by a fatty band which passed directly over it, and which seemed to be a part of the mesentery of an adjacent coil. The contents of the abdomen were thoroughly examined, and it was demonstrated that there was entire absence of any recurrence of the cancer. An instance of such long-continued immunity is most encouraging, and serves to stimulate to greater boldness and to more radical thoroughness of excision.

A Discussion of the Relation Between Human and Bovine Tuberculosis, with Special Reference to Primary Infection in Children Through the Alimentary Tract.—A. D. Blackader reviews the literature of the subject, taking up both sides of the question. He concludes that in the past the general profession has undoubtedly exaggerated the danger of infection from ordinary milk. Other acid-fast bacilli have been taken for true tubercle bacilli, and we have also been unduly afraid of a few bacilli in otherwise normal milk. It is also to be remembered that tubercle bacilli do not develop in milk under ordinary circumstances, as many other microorganisms do, and that their virulence is inhibited by the many modes in which the milk is prepared for the child. Adami suggests that in the slowly progressive forms of the disease, bacilli taken in the food, especially bovine bacilli, may by long residence in the human body acquire increased proliferative powers and toxicity against the human tissues. The author is convinced that much clinical and bacteriological work still remains to be accomplished before the latest statements of Koch can be either accepted or contradicted.

The Formation of Cysts in the Faucial and Pharyngeal Tonsils.—J. L. Goodale reports two cases in which histological examinations were made of the growths removed. In the first, the cavity was lined with stratified pavement epithelium in the interior of the adenoid, lying directly below a short, abruptly terminating furrow or crypt, the mucous membrane at the base of the latter extending nearly to the wall of the cavity. It seems reasonable to infer that the cavity represents a former portion of the crypt, and has been cut off by the adhesion of the walls of the latter near its orifice. It was evident from appearances that a heightened pressure existed within the cavity. In the second case there was a cavity lined with pavement epithelium, occurring in the middle of the tonsil which showed advanced atrophy of its lymphoid tissue with fibrous changes in the reticulum. These findings render it probable that the formation of the cavity was dependent on the occlusion of a pre-existing crypt, either by old fibrous contraction or by adhesion of its walls through inflammation, or by the covering of its orifice from a fold of overlying, adherent membrane. In both cases, there was absence of acute inflammation in the vicinity of the cavities.

Journal of the American Medical Association, Dec. 21, 1901.

Treatment of Neurasthenia.—H. N. Moyer would first secure the patient's confidence, and then employ persistent suggestion—not hypnosis. The patient should not be allowed to discuss his ailments with any one except his physician, while the latter should keep up a careful regulation of the former's mode of living. Rest is the sheet anchor in treatment, though some patients do well to indulge moderately in golfing. Milk and eggs, where digested, are of special dietetic value, and several glasses of water should be taken during the day. While drugs are, as a rule, of little value, some cases are benefited by strychnine in large doses. Agitation and insomnia call for the bromides. Hydrotherapy is beneficial. Exposure to cold air under the precautions employed in tuberculosis has, in the writer's hands, proved of great benefit.

Intracellular Occurrence of Diplococcus Pneumoniæ in Cerebrospinal Meningitis.—Two cases occurring in human beings and two in horses are mentioned by L. B. Wilson. Microscopical examinations of preparations made from the cases show that it is possible occasionally for diplococcus pneumoniæ to occur abundantly within the cells of the exudate in meningitis. This may indicate a closer relation than is ordinarily supposed to exist between diplo-

coccus pneumoniæ and diplococcus intracellularis meningitidis. The point merits further investigation. The position of the coccus relative to the cell is occasionally of less importance than its shape, arrangement, staining reactions, or cultural characteristics. Pathogenesis in all its phases as yet has been insufficiently studied to be of much help in differentiating these microorganisms. It would certainly appear that great care must be exercised in diagnosing, from direct cover-slip preparations of meningeal exudates, between diplococcus pneumoniæ and diplococcus intracellularis meningitidis.

Corneal Lesions in Acquired Syphilis.—Three clinical histories are related by W. H. Wilder. He notes that the clinical features of acquired syphilitic keratitis vary. Different writers have described cases of diffuse interstitial keratitis differing in no essential particular from the lesion as seen in inherited syphilis, except that it is more frequently unilateral, and the degree of vascularization is much less. Iritis may or may not be associated with this form. More distinctive, however, is the form in which the lesion develops at some point of the corneal circumference as a rather dense grayish infiltration, which remains limited to this part of the cornea, passing through all its phases with no tendency to ulceration. Sometimes the dense opalescent opacity may extend quite up to the margin of the cornea and appear to be merged in the sclerotic; in other cases there may be a clear space between the site of the lesion and the limbus. In this form of the disease, vascularization is not a prominent feature, and is absent in most of them. Iridocyclitis and choroiditis may be associated with this condition, so that this form may be the same as that described under the name of "keratitis interstitialis punctata."

Therapeutic Indications Suggested by the Condition of the Blood.—O. T. Osborne briefly reviews the physiology of the blood, and claims that a proper management of the circulation is all that is necessary in many conditions of disease. But we are apt to neglect many potent and simple procedures. For instance, in febrile processes we are not careful enough to keep the blood or the skin where it cools, and keeps down the temperature, and therefore saves the waste which high temperature will cause. Again, the condition of vasomotor ataxia plays an important part in many functional disorders, notably in neurasthenic persons. When the blood should be at the surface, the surface vessels are contracted, and there is too much blood in the internal organs, perhaps notably the brain, as at night, causing insomnia; when there should be anæmia of the surface, there is a flushing of the skin in these cases, giving sleepiness in the daytime, and perhaps an imperfect digestion, constipation, and other functional disturbances. This condition of vasomotor ataxia seems to be present in marked degrees in most cases of hysteria. Osborne further states his conviction that neurotic and possibly hysterical cases have an increased thyroid secretion, and that various functional disturbances, such as palpitation, cerebral irritability, insomnia, sweating, nervousness, hot flashes, muscular weakness due to lack of blood-vessel tone, can be due and is due to this increased secretion. On the other hand, he feels that continued high tension of the arteries, with the consequent chronic endarteritis, gouty and atheromatous conditions, can be due in later life to the diminution of the thyroid secretion, and the predominance of the suprarenal secretion, causing the contraction of the peripheral blood vessels.

New York Medical Journal, December 21, 1901

Amygdalotomy Rash.—E. A. Forsyth records the history of a boy of eleven, from whose pharynx adenoids were removed under cocaine anæsthesia. All antiseptic precautions were observed. The second day after operation a rash appeared on the face, neck, and chest, with slight fever. Scarlatina was suspected, but the child was perfectly well in two days.

Medical News, December 21, 1901

The Biological Relationship of Proteids.—P. A. Levene speaks of the new work of Uhlenhuth, which indicates that there is a biological similarity between proteids having a different chemical individuality, but obtained from the same animal. The results obtained in the writer's laboratory indicate that chemically different proteids derived from the same or closely related animals have the power of producing similar "precipitins" when injected into animals. The writer thinks that human milk could be used for obtaining serum for the detection of human blood.

Artificial Milks.—Louis Kolipinski declares that without milk the treatment of many diseases is futile. It is a complete and perfect food. Its sole and persistent use is directly curative. Physically, milk is the most perfect of emulsions. Chemically, its ingredients are so proportioned as to satisfy every organ of digestion and nutrition. The formula which is given in this article represents a milk that contains all of the component parts of the natural animal secretion. The product is cheap, and easily and readily prepared. The ingredients are easily obtained. They should be fresh and palatable and sterile. The formula is: Extract of malt (sirupy), one tablespoonful; olive oil, one tablespoonful; roasted flour, two teaspoonfuls; one broken raw egg. Beat up in a bowl or dish with a spoon or egg-beater for three or four minutes. Add by degrees, while stirring, a tumbler or gobletful of pure cold drinking water. Season with salt. To be taken one or two hours after meals. In hot weather add crushed ice. This general formula is modified in various ways according to the case. The flavor is rich and the aftertaste pleasant. This milk is very useful in temporary exhaustion, mental or physical. It is an excellent galactagogue. For the use of travellers, explorers, and sportsmen, the milk is also theoretically well adapted.

Philadelphia Medical Journal, December 21, 1901.

The Value of Blood Examination in Diagnosis.—Frederick J. Kalteyer reviews the recent article on blood examination by Dr. Deaver and Dr. Moore, and states that to the medical man unfamiliar with the methods of blood examination the article may suggest adverse criticism as to the value of these examinations in diagnosis. He believes that it is reasonable to infer that the more irregular the symptoms of tertian or quartan fever, the less difficult should be the finding of parasites in the blood, for in these cases sporulation continues over a longer period than in typical cases. The writer speaks of the technique of obtaining blood for examination, and states that the pain and discomfort of this operation are scarcely more than are caused by the subcutaneous insertion of a hypodermic needle. He believes that the diagnosis of ulcerative endocarditis may be aided if pyogenic cocci are isolated from the blood. He declares that the agglutination test in typhoid fever is often of decided advantage, especially in atypical cases. As to the value of the estimation of hæmoglobin, he thinks that a general anæsthetic should not be given, except in cases of absolute necessity, when the hæmoglobin is low. He refers to a case in which the leucocytic count was low, but in which an abscess containing 500 c.c. of pus was found at operation. His explanation is that the abscess was thoroughly walled off. The fact is well established that in cases of this kind the leucocytic count is generally low.

Hepatic Drainage.—John B. Deaver and Edward Kemp Moore declare that the surgery of the gall-bladder and the bile ducts is still in the stage of development. Diseases of these parts are remarkably frequent in their occurrence. Gall-bladder disease shows itself in fully as many different forms as appendicitis, and it calls for the most careful study. The symptoms of pericholecystitis depend in great measure upon the adhesions which exist. These should be freed, but the prevention of the reappearance of these symptoms will be accomplished by attention to their cause—defective drainage of the gall-bladder and liver. Whatever the nature of the symptoms, then, their cure will lie in the establishment of free hepatic and cystic drainage. The success in the treatment of gall-stone disease depends upon the ability to institute and maintain free drainage. The reputation of the Sprudel Spring, at Carlsbad, for the cure of gall-bladder troubles, is owing to the ability of this water to free the hepatic drains from infection, thus reducing inflammatory tumefaction and making room for the establishment of free drainage. The pathological lesions still persist. The gall-bladder is an organ with very little function in the human race. In the late stages of cholangitis it is imperative to open freely and drain the bile ducts, for it is only in the free escape of the infected bile that there will be any hope for the cure of the condition. In early cases of gall-bladder disease, before the occurrence of any marked anatomical changes, temporizing and Carlsbad are indicated; but in the late stages, temporizing is dangerous.

A Case of Morphine Poisoning; Successful Employment of Cocaine as an Antidote.—Albert C. Barnes reports this case of a girl aged seventeen years. She was engaged in moulding finely powdered morphine sulphate into hypodermic tablets. About two hours after beginning the work, she began to show the symptoms of morphine poisoning. Unconsciousness became profound. The respiratory and cardiac functions were extremely depressed. The usual restoratives were applied before the writer was called. The primary effects of toxic doses of cocaine are directly antagonistic to the late effects of toxic doses of morphine, and so cocaine was employed. This drug stimulates the respiratory centers, the heart, and vessels by direct action, and, by a specific effect upon the accelerator mechanism, produces in-

dose. Quinine was sometimes taken to avert a future attack, but not sooner than an hour after the administration of the iodine mixture.

Revue de Médecine, October 10, 1901.

Rare Complications of Dysentery.—Paul Remlinger reports in detail some rare complications or sequelæ of dysentery, such as nephritis, anasarca, arthritis, epididymitis, phlebitis, and splenic abscess. In the first case reported from the post-mortem results, it is evident that the chain of events was as follows: Dysentery, acute nephritis, articular and muscular rheumatism, toxic pulmonary lesions. There were two cases of anasarca, which at first suggested nephritis, but no albuminuria was found. There was, however, a lessened amount of urea, and of solid substances, and the methylene-blue test indicated a disturbed condition of the renal filter. The treatment usual in cases of nephritis caused improvement in all the symptoms.

Hysterical Stammering.—Georges Guillain reports the case of a man of forty-five years, without nervous family taint, but who had become extremely emotional and nervous since the death of his wife in 1889. In 1896, he fell at night in a badly lighted street, and although he was apparently uninjured, forty-eight hours later he had complete paralysis of the upper and partial paralysis of the lower limbs, with dysarthria. Two months later the paralyses disappeared as rapidly as they had come, but the disorders of speech remained. When seen four years later, he was in excellent health, but affected with a species of stammering and in addition had intermittent periods, when the grammatical arrangement of phrases was difficult, and when words were forgotten. He could not put out his tongue or move it laterally, and any effort to do so would cause a spasm. The affection is deemed hysterical by the author.

Revue de Chirurgie, October 10, 1901.

A Case of Staphylococcæmia.—E. Reymond and M. Alexandre report the case of a man who was suffering from an abscess in the dorsal region. Staphylococci were found in the pus of the abscess, in the blood, and in the urine. The abscess followed the appearance of boils of the left arm and axilla that were not operated on, and to which the generalized infection was undoubtedly due. The secondary localization of staphylococci is apt to be influenced by local fatigue, contusion, or congestion. In this case the abscess was situated in the dorsolumbar muscles, which were constantly exercised, as the patient was a baker.

Goundon.—M. Jeanselme says that this name is given to two bony, ovoid, symmetrical tumors which arise at the root of the nose on each side, and by their growth narrow the nasal fossæ and interfere with vision. It occurs among the negroes of the Western Coast of Africa, and begins usually in late childhood, being accompanied at the onset by violent headache, slight epistaxis, and mucopurulent discharges from the nose. Later these symptoms disappear, but the tumors progress. They are formed of areolar or spongy tissue, covered with a thin layer of compact tissue. Goundon is not due to syphilis, tuberculosis, or leprosy, nor is it hereditary. Its origin is as yet unknown.

A Case of Goundon.—Pacheco Mendès reports a case of this affection, consisting in a tumor situated at the left side of the nose, osseous in nature, and of the size of a pigeon's egg. The tumor was removed by operation. The author reviews the literature and history of the subject, and concludes that the disease is one peculiar to the negro race, and belongs to the class of trophoneurotic lesions of the jaw. Section of the inferior maxillary nerve has been known to determine hypertrophy of the maxillary bone of the same side. There is, therefore, nothing unreasonable in the supposition that goundon is due to a central nerve lesion which causes peripheral vascular troubles that induce an exaggerated nutrition of the bone and periosteum.

The Practitioner, December, 1901.

Bright's Disease in Children.—Henry Ashby urges systematic examination of the urine in sick children. The common type of nephritis in early life is the acute or subacute type of inflammation with exudation of blood and fibrin, which more or less choke the tubules, and the urine, in consequence, is dark in color and albuminous. Chronic nephritis is much less common, and granular contracted kidney, chronic from the beginning, and associated with cardiac hypertrophy and vascular changes, occurs but rarely. There is the septic form of nephritis with local rather than general inflammation, the chief feature of which is an exudation of leucocytes from the vessels, and sometimes minute points of suppuration; and there are toxic degenerative changes associated with the acute febrile disorders, especially diphtheria, though these can hardly be classed with nephritis. The author describes each variety in detail.

Some Affections of the Nervous System in Connection with Renal Disease.—F. E. Batten says that in the course of acute, but more especially chronic, nephritis, various nervous phenomena manifest themselves, the most common of these being uræmic convulsions. The presence of aphasia, word blindness, loss of vision, hemiplegia, or, in rare cases, loss of power on the one side and spasmodic twitching on the other, have all been observed. Of the various theories held in regard to the cause of the paralysis following convulsions, that which attributes the condition to a chemical poison produced within the body, owing to the want of normal elimination by the kidneys, is that which most readily accounts for the headache, the eclampsia, the coma, and the general symptoms. The psychoses which occur in uræmia are apt to be either mania or melancholia. Cases of insanity of uræmic origin are, on the whole, rare. As to the frequency of renal disease among the insane, an examination of 1,034 patients showed that in 60 per cent. albumin or casts were present.

The Treatment of Bright's Disease.—William Hale White considers the treatment of acute Bright's, of chronic tubal nephritis, and of chronic interstitial nephritis, giving details as to diet, clothing, climate, habits, and the treatment of special symptoms. In acute nephritis the diet should always be milk, because it is simple and unirritating, is suitable for fevers (Bright's in its acute form is often accompanied by pyrexia), and because it is a fluid, and it is important to wash out the renal tubules and so get rid of all the epithelial débris that blocks them. The patient may well take four pints of milk in twenty-four hours. He should have it every hour, and it does not follow that he is doing badly if the urine contains numerous casts; indeed, the reverse is often the case. In chronic tubal nephritis patients should not be kept too rigorously to milk, but be allowed a little meat, bread and butter, and simple pudding. In chronic Bright's, as we do not know the cause of uræmia, the best way to avoid it is to give such diet as will keep the patient in the best general health, which will generally be such a combination of fats, carbohydrates, and proteids as is usually desirable in health.

The Ocular Symptoms in Bright's Disease.—Walter H. H. Jessop thus enumerates the ocular symptoms in Bright's. The naked-eye appearances are those of œdema of the lids, especially the lower, which is of a fugitive nature. The eye has often a bright, shining, watery appearance, due to conjunctival changes. Spontaneous hemorrhages beneath the conjunctiva and in the substance of the lids are not infrequently to be found. *Albuminuric retinitis* is usually bilateral, and is most often met in chronic interstitial nephritis, but is also found in parenchymatous nephritis, especially when associated with pregnancy and scarlet fever. As to vision, patients rarely, if ever, become blind from the changes in the retina. Very few cases live beyond two years after the retinitis has been diagnosed; but it must be remembered that as the acuity of vision is seldom much affected at first, many patients would not seek advice until the disease was well advanced. *Uræmic amaurosis* is, as a rule, bilateral, and comes on suddenly, clearing up in a few days with complete restoration of sight.

Pregnancy and Albuminuria.—D. Berry Hart says that when albuminuria is present, milk diet and rest in bed, with attention to the bowels and an occasional hot bath, are all that is necessary in the way of treatment, cases so treated seldom going on to the more serious stages. When, however, the case becomes worse, and headache or eye symptoms supervene, with the urine still albuminous, induction of labor is indicated. As to eclampsia, the author is convinced that such heroic remedies as powerful purgatives, the use of pilocarpin, or venesection are a mistake. Renal, pulmonary, and cardiac conditions should be ascertained, the temperature and pulse observed, and any paralytic condition ascertained. Hypodermic injections of morphine should be given, beginning with ½ to ⅔ grain, repeating in two or three hours if necessary, but with only ¼ grain. Not more than 1 to 2 grains should be given in the twenty-four hours. Next give a large saline injection by the bowel, or, if necessary, a submammary transfusion of two to three pints of a saline (3j. of salt to each pint). One smart purge may be given, but pilocarpin is dangerous, as it may increase lung œdema, and cause a distressing accumulation of saliva.

Annals of Surgery, December, 1901.

Note on X-Ray Burns and Their Treatment.—T. W. Huntington enumerates the views at present held as to the nature and pathology of this class of injuries, and relates one case cured by excision of the affected area

and skin-grafting. He says that if excision of the ulcer be determined upon, it must be performed with extreme boldness to the end that all tissue supplied by defective blood-vessels be removed. He also alludes to the value of silver-foil dressing for Thiersch grafts. It is dry, aseptic, and mildly antiseptic; but its chief value seems to lie in its efficient prevention of adhesion of the gauze to the grafts.

Treatment of Tuberculosis of the Peritoneum.—This is a historical review of the question by C. Fengar, who adds certain comments based on his personal experience. He says that the advantage of laparotomy over puncture, as regards its effect on the exudate, is probably more apparent than real. It seems likely that the termination of the progress of the tuberculous process is the main factor in the causation of improvement, and in one or the other of these conditions the method of evacuation of the exudate is immaterial. The frightfully disappointing results of the energetic surgical treatment of peritoneal tuberculosis—curetting, excision of tuberculous tumors in the omentum, adhesions, and mesenteric glands—must teach us that nature cures tuberculosis of the peritoneum better than the surgeon.

Pathology, Symptomatology, and Diagnosis of Tuberculosis of the Peritoneum.—D. E. Eisendrath enumerates four pathological varieties of this affection as follows: (1) Hæmatogenous or disseminated miliary form. This generally occurs as a part of a general miliary tuberculosis, characterized by small grayish nodules scattered universally over the peritoneum and omentum, each surrounded by a hyperæmic zone; (2) A local lymphogenous form most frequently secondary to an intestinal tuberculosis, less frequently to that of the mesenteric glands, retroperitoneal glands, or vertebræ. This is characterized by grayish or yellowish tubercles which follow the course of the lymph vessels closely, and are often arranged in rows on the intestine. The tissue around the same is hyperæmic, at times there are a few hemorrhages, often they are covered by granulation tissue or fibrin; (3) The third form is exudative in character. We find in the peritoneal cavity a more or less serous, sero-fibrinous, or, if there is mixed infection present, even purulent exudate. In some cases, especially in alcoholics, the exudate may be hemorrhagic. There is often a very thick eruption of grayish tubercles, the remainder of the peritoneum being more or less covered by a fibrinous exudate; (4) The adhesive form, sometimes spoken of as the fibrous form. This is the slowest in development; it is the most frequent in children, and there is usually no ascites present. It is characterized by the formation of fibrinous membranes, inclosing tubercles with extensive adhesion of the intestinal coils to each other, to the solid viscera, and to the parietal peritoneum.

Differentiation Between Inflammatory Processes and Neoplasms of the Bones by the Röntgen Rays.—In a series of excellent skiagraphs, Carl Beck illustrates the points suggested by the title of his paper. He says that many limbs have been sacrificed by unnecessary amputation, and many lives lost by deferred amputation on account of errors in differentiating the various inflammatory processes from the growths of the bones and joints. The Röntgen rays have opened entirely new fields in this sphere. If they cannot always give a positive answer, they often, by the method of exclusion, increase the chance of arriving at a correct diagnosis. If in a case of an obscure swelling of the knee-joint, for instance, the Rontgen rays reveal no impairment of the integrity of the joint, ostitis, tuberculosis, syphilis, or a bone injury can be excluded. It is certain, then, that only the soft tissues are involved. Thus we may, in conjunction with other clinical symptoms, be satisfied that we have to deal with a rheumatic swelling, for instance. But in many instances the Rontgen rays give a positive information. Again, in periostitis as well as in osteomyelitis the skiagraphic signs are well marked. Abscesses cannot be localized, but their extent is also so well outlined that the technical steps of the operation can be definitely traced in advance. The feeling of security the surgeon has while proceeding under the mentorship of the skiagraph gives a satisfaction unknown in former years, when often the whole femur, for instance, has had to be exposed simply in order to ascertain whether all foci were detected. If the Röntgen rays show but one focus, no other regions of the bone need be attacked. In arthritis deformans the osteitic proliferations are easily recognized by means of the rays. In tuberculosis the latter give information, not only as to the seat and extent of the tuberculous areas, but also offer means, and at times the only means, of differentiation from other affections with similar clinical signs. In the differentiation of the various forms of sarcoma, the rays are of the greatest value. It is true that the skiagraphic characteristics described are not expected to serve as substitutes for our well-tested clinical methods of diagnosis, but should be regarded as valuable adjuncts in general, and sometimes as determining factors in doubtful cases.

Archives of Pediatrics, December, 1901.

Primary Intestinal Tuberculosis in Children; Its Frequency and the Evidence of Its Relation to Bovine Tuberculosis.—David Bovaird concludes from his investigations: (1) That English reports alone show any considerable number of cases of primary intestinal tuberculosis; (2) That it is a very rare affection among children in or about New York, little more than 1 per cent. of the cases of tuberculosis having this origin; (3) That the proportion of tuberculous cases found at autopsy in New York is lower than that of European observers; (4) That the evidence connecting tuberculosis among children with the consumption of the milk of tuberculous cows is very scant.

Great Fluctuations in Temperature in the Terminal Stage of Pulmonary Tuberculosis.—Samuel S. Adams reports eight cases in which the temperature charts illustrate the apparent harmlessness of wide fluctuation of temperature in the terminal stage of the disease. The temperature may reach 108° F. and in a few hours drop to 95° F. without any apparent effect upon the child, either mentally or physically. Such wide variations have occurred in some of the cases without disturbing their appetite, disposition, intelligence, or play. It is not unusual to see a child enjoying his breakfast with a rectal temperature too low to be registered by the thermometer, and to find him eating his evening meal with relish in spite of the fact that his rectal temperature is now 106° or 107°. The absence of evidence of collapse and of the usual phenomena of hyperpyrexia can only be explained upon the assumption that some irritant acts upon the heat centers differently from that present in purely septic conditions.

Treatment of Tuberculosis in Infancy and Childhood, with Special Reference to the Use of Guaiacol.—B. K. Rachford holds that this drug far outclasses all others in the treatment of tuberculosis. The prescription which he uses is the following: ℞ Guaiacol, 3j.; lanolin, 3ij.; lard, 3v. One level teaspoonful to be rubbed into the chest at bedtime each day. Guaiacol is one of the few drugs which when applied to the skin is rapidly absorbed by the lymph channels, and thus into the general circulation. This treatment is of the greatest value in all forms of lymphatic tuberculosis. In tubercular peritonitis the good results commence at once; and the patient, as a rule, slowly but steadily recovers. When the active symptoms are in abeyance, the author usually substitutes carbonate of guaiacol internally for the inunction treatment. It is easy of administration, mixed with a little milk-sugar, and is valuable in all forms of tuberculosis in infancy and childhood, but especially in the treatment of intestinal and mesenteric tuberculosis. Guaiacol holds first rank as an intestinal and as a pulmonary antiseptic.

Zeitschrift für Klinische Medicin, Bd. 44, H. 3 und 4.

Etiology of Myelitis.—L. Huismans says that myelitis is exclusively of bacterial origin. The view formerly held that intoxication by various chemical poisons can produce myelitis is erroneous. These agents are capable of producing only a predisposition to myelitis or of increasing a susceptibility already existent. The predisposition to this disease consists in a natural or acquired condition of the spinal blood-vessels which favors thrombosis. Acute myelitis follows various forms of embolism. Chronic myelitis appears as a sequel to primary arterial thrombosis. While both acute and chronic myelitis are due to bacterial infection, in only the latter is a predisposition as previously mentioned necessary. The acute form either subsides into a non-irritating sclerosis or passes into the chronic form. In many cases the condition pursues a chronic course from the beginning.

Pathogenesis of the Micrococcus Catarrhalis (Pfeiffer).—A. Ghon and H. Pfeiffer report the bacteriological study of this microorganism, together with the clinical observation of five cases in which it was present. This coccus without the assistance of other microbes is able to produce simple bronchitis, bronchopneumonia, and the clinical picture at least of lobar pneumonia. In addition to the local symptoms, evidences of general infection may be present. The objective and subjective appearances produced by this microorganism are entirely similar to those seen in infections due to the influenza bacillus and pneumococcus. Bacteriological examination is necessary in these cases in order to determine the exact bacterial excitement. Many cases show a mixed infection with these three microbes. In other cases the micrococcus catarrhalis is present merely as a saprophyte.

Book Reviews.

WHAT A YOUNG WIFE OUGHT TO KNOW. By Mrs. EMMA F. ANGELL DRAKE, M.D., Graduate of Boston University Medical College. Phila.: The Vir Publishing Company.

THIS little book is one of a set comprising "A Self and Sex Series." It is written for woman by a woman. It contains nothing either to commend or to condemn, except that the repetitions are so very numerous making their perusal exceedingly tiresome.

MODERN OBSTETRICS: GENERAL AND OPERATIVE. W. A NEWMAN DORLAND, A.M., M.D., Assistant Demonstrator of Obstetrics, University of Pennsylvania; Associate in Gynecology, Philadelphia Polyclinic. Second edition, rewritten and greatly enlarged. Cloth, 8vo, 797 pp., with 201 illustrations. Philadelphia and London: W. B. Saunders & Co., 1901.

A COMPARISON of the present volume with its predecessor shows evidence of careful revision and many additions, which bring it fully up to date.

The important subject of puerperal sepsis is carefully elaborated, especial attention being paid to the most recent views with regard to pathology and treatment.

Chapter VI deals with the pathology of the new-born in a clear and thorough manner. Puerperal eclampsia is considered at length, attention being given to the modern theory of autointoxication. The sections on prophylaxis and treatment are well written, as are also the chapters on ectopic gestation, the induction of premature labor, and the manual dilatation of the cervix.

The chapters on operative obstetrics are entirely in the line with the most approved modern teaching. As an evidence of the thoroughness of the revision, we find a careful description of the condition known as *deciduoma malignum*.

The chapters on the physiology, hygiene, and mechanism of labor are duly elaborated. The illustrations (many of which are new) are clear and helpful, the style is direct and pleasing.

PEDIATRICS, THE HYGIENIC AND MEDICAL TREATMENT OF CHILDREN. By THOMAS MORGAN ROTCH, M.D., Professor of Diseases of Children, Harvard University. Third edition. Philadelphia and London: J. B. Lippincott Co., 1901. 8vo, pp. 1,021.

THE third edition of this admirable work has been entirely rewritten and rearranged, placing it as a whole in the front rank of pediatric literature. While the changes in many respects have been quite radical, they add very materially to a more thorough and systematic study of the different subjects, especially those which refer to symptomatology, diagnosis, and treatment. In so far the practical value of the work is very much enhanced. As might be expected, a great deal of space is devoted to the anatomy and physiology of early life, and to the advances which have been made in infant feeding, in bacteriology, and in the bacteriological study of the blood. The subject of substitute feeding and the use of laboratory modifications are very exhaustively discussed from a distinctly authoritative standpoint, and much valuable and suggestive information is offered to the reader concerning the fundamental principles governing all kinds of artificial alimentation. The text is plentifully supplied with illustrations and the colored plates are admirably well done. The general practitioner who desires an up-to-date work on pediatrics will find this one admirably suited to all his practical needs.

DISEASES OF THE UPPER RESPIRATORY TRACT, THE NOSE, PHARYNX, AND LARYNX. By P. WATSON WILLIAMS, M.D., Lond., Physician in charge of the Throat Department at the British Royal Infirmary, Physician to the Bristol Institute for the Deaf and Dumb. Fourth edition, illustrated. New York: Longmans, Green, & Co; London and Bombay, 1901.

THE work, in its fourth edition, has been much enlarged and brought fully up to date. There are twenty-eight plates, many of which are colored, and two hundred and seven illustrations in the text. Eighteen stereoscopic plates are given, which, when viewed through the stereoscope that accompanies the volume, give a most realistic idea of form and dimension. The idea of including stereoscopic views and fitting each volume with a stereoscope is novel and effective. The volume is one of 436 pages, and is an excellent example of the printer's art—paper good, type clear and large, and the illustrations better than the average. The text is in excellent English, is simple, clear, and direct. A thorough acquaintance with the subject is manifest. The essential portion of the text is printed in large type, while "matters of detail" are in smaller type and may be considered only as an elaboration of the main part of the text.

Illustrations appear wherever they are of value in aiding to elucidate the text. They have been chosen with rare judgment. The first chapter is devoted to a description of the anatomy, histology, and physiology of the upper air passages. Then follows a chapter on the methods of examination employed in relation to these parts; after this the various chapters devoted to the consideration of the diseases of the upper air passages follow in logical order. The author does not lose sight of the relation of the system at large to diseases of the upper respiratory tract. The advice given is of a conservative nature and is safe to follow. Chapters of particuar interest are those on diphtheria, the neuroses of the various parts, the various paralyses met with, and diseases of the accessory sinuses of the nose. An appendix giving formulæ and therapeutic methods, also directions for post-mortem examinations, is found. The work is an excellent one and deserves a place among the "active" volumes of every medical man's library.

PRACTICAL X-RAY WORK. By FRANK T. ADDYMAN, B.Sc. (Lond.), F.I.C., Radiographer to St. George's Hospital, Member of the Röntgen Society of London, etc. With fifty-two illustrations and twelve full-page plates. London: Scott, Greenwood & Co., 1901; New York: D. Van Nostrand Co.

THIS book is a treatise on the subject of the *x*-ray from the point of view of the physicist and electrician, rather than the medical man. The clinical use of this form of radiant energy is only considered secondarily, while most of the space is given to a consideration of the methods for developing, using, and controlling the rays and to the various forms of apparatus which are likely to prove most satisfactory. This has only a secondary interest for the physician or surgeon, to whom clinical use and results must always be of first importance. One important point which receives adequate discussion relates to the localization of a foreign body in the tissues, as to depth, and to other objects whose shadows are seen. This is a matter of much importance in surgery, and is one which is not often discussed clearly. Precise directions are given for the preparation of plates and the printing therefrom, and a number of excellent reproductions of printing from *x*-ray negatives are introduced into this chapter. The book forms an interesting monograph on the subject of *x*-rays, and familiarity with its contents will enable us to make a success much greater than usual in our use of this remarkable force.

MATIÈRE MÉDICALE ZOOLOGIQUE. Histoire des Drogues d'Origine Animale. Par H. BEAUREGARD, Professeur à l'École Supérieure de Pharmacie de Paris. Révisé par M. Coutière, avec préface par M. D'ARSONVAL. Paris: G. Naud, éditeur, 1901.

THE author has here accomplished a most delicate task, presenting a history of the animals and drugs of animal origin employed in therapy. An immense amount of research and careful study is incorporated in the 388 octavo pages, which are embellished with excellent drawings and interleaved with plates, several of which are in colors. The author has left for himself in this work a lasting monument, having corrected the proof sheets on his deathbed. A fitting introduction in the nature of a eulogistic discourse presents the work to the medical and scientific public.

PROGRESSIVE MEDICINE, a Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, etc., assisted by H. R. M. LANDIS, M.D., Assistant to the Out-patient Department of the Jefferson Medical Hospital. Vol. III., September, 1901. Philadelphia and New York: Lea Brothers & Co., 1901.

FOUR contributors have furnished the manuscript for this number, which takes in diseases of the thorax and its viscera, including the heart, lungs, and blood vessels, dermatology, and syphilis, diseases of the nervous system, and obstetrics. The authors are William Ewart, William Gottheil, Richard Norris, and William Spiller. That the work of each has been well done goes without saying. One hundred and thirty-three pages are required for the first retrospect, which begins with croupous pneumonia and ends with aortic aneurysm. Gottheil has given an excellent résumé of new things in his branch, and has made a special feature of illustrations, which is commendable. Spiller's review of nervous disorders is worth reading from start to finish, and Norris has covered the ground of obstetrics and its disorders in an acceptable manner.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, December 9, 1901.

JOHN B. WALKER, M.D., CHAIRMAN.

A Case of Hemorrhagic Pancreatitis with Fat Necrosis; Operation.—Dr. H. LILIENTHAL presented a man, fifty-three years of age, who had been admitted to the Mount Sinai Hospital on June 4, 1900. Nineteen years before, he had had an alleged similar attack to the present one. Nine days before admission, the attack had begun with cramplike pain in the abdomen and a chill. There was constipation, with light-colored stools. On examination, the abdomen had been found very much distended and rigid, and especially tender in the right hypochondrium. Here there was a mass which was dull on percussion. The pulse was 104 and the temperature 101° F. There was slight conjunctival icterus, and the man looked extremely ill. The following day an incision was made with the idea that the gall-bladder was the organ at fault. However, on exposing the omentum, there were found numerous circular indurated plaques, ranging in size from that of a pin's head to more than 1 cm. in diameter. On introducing the hand, the mass was found near the head of the pancreas, and on aspiration, blood was withdrawn. One of the plaques was cut out for examination. There was a large quantity of bloody fluid in the abdomen. The wound was closed with drainage. The man had been discharged well on June 30. Examination of the specimen by Dr. F. S. Mandlebaum showed the case to be a typical example of fat necrosis.

Cases of Intussusception.—Dr. LILIENTHAL presented three cases of intussusception. The first was a boy of three years, seen by him on January 30, 1901. There was a history of abdominal cramps for eight days previously. There had been but little vomiting; the temperature was 100°, and there was a peculiar transient cyanosis at times. There had been no blood in the stools. Suspecting intussusception, the child had been sent into the hospital. The next day it had become extremely cyanotic, and the pulse very rapid, so an incision had been made along the outer border of the rectus. This had exposed an ileocæcal intussusception about eight inches long. The appendix being large and œdematous, it was removed, and the cæcum was anchored to the lower end of the wound by a single suture. At the end of sixteen days, the child had been discharged from the hospital.

The second case was that of a boy of three years, who was shown because of the interest attached to the diagnosis. The boy had been discharged from the Mount Sinai Hospital on March 10 as cured after an alleged attack of typhoid fever, associated with a neuritis and a partial hemiplegia. On April 14, at noon, he had been readmitted with a history of having been well up to the previous noon, when he had been seized with a desire to go to stool. A few hours after this, he had had bloody stools. Rectal examination had been negative, but had been followed by a copious discharge of blood and mucus. The operation had been done at 4 P.M. the same day, an incision being made along the outer border of the rectus on the supposition that there was a mass on that side. This incision had exposed a distended gall-bladder and an intussusception of the ileocæcal variety. It had been reduced with considerable difficulty, and the upper part of the cæcum had been anchored by a single suture to the lower angle of the wound. The child had recovered perfectly. The speaker said that he favored making the incision on the right side if it were thought that the tumor was on that side, but if it appeared to be in the middle or on the left side, he employed a median incision.

The third case was a female infant, five and a half months old, who had been admitted to the hospital on October 18, after having been seen by Dr. Koplik. A diagnosis of intussusception had been made. The child's eyes looked sunken. An immediate operation had been done through a median incision, and this had revealed an ileocolic intussusception. The reduction had been effected with great difficulty. The child had been discharged one week later.

Supracoracoid Dislocation of the Humerus.—Dr. CARL BECK presented a man with a supracoracoid dislocation of the humerus, which had been sustained six months ago, and had been treated by a druggist for about five months as a contusion. It had only been after incision and extensive dissection that he had been able to reduce the dislocation, and in order to make this permanent, he had sawn off the head of the bone and inserted a silver wire suture.

Gangrenous Intussusception in a Child of Four Years; Intestinal Resection; Recovery; a Method of End-to-End Suture.—Dr. CHARLES N. DOWD presented this case and read a brief paper in connection with it. The child had been well up to May, when he had begun to suffer from abdominal pain and discomfort. When first seen by Dr. Dowd in July, there had been chylous vomiting, and the child had been losing flesh and strength rapidly for the past ten days, and the bowels had not moved in this time. The pulse was 120 and the temperature 100°. Tympanites was excessive. He had operated at once through a median incision below the umbilicus. Greatly distended and congested coils of intestine had rolled out, and an intussusception had been found at about the middle of the ileum. There was a spot of gangrene through which a perforation was discovered after making gentle manipulation. Two inches of this portion of the intestine, together with some omentum, were resected and a circular enterorrhaphy done. The patient had been put to bed in fairly good condition, and the next day the bowels had moved. The child had left the hospital in about one month.

The speaker said that recovery from non-reducible intussusception, and especially with a gangrenous intussusceptum, in young children was very rare. The formation of an artificial anus was fast losing favor and was not to be recommended as a rule in cases of intussusception. It takes almost as long to do that operation as to suture the resected ends of the intestine together. Unless the artificial anus was in the lower part of the intestine, life was maintained with difficulty. The most favorable results had been obtained by resection and circular enterorrhaphy. The modes of performing intestinal suture were various; one author had enumerated no less than eighty-one different methods of intestinal suture. The Murphy button usually gives satisfactory support and good union, and each year finds this device more generally employed by surgeons; however, there were certain conditions to which it was not well suited. There were numerous method of end-to-end suture, the Czerny being the one most commonly employed. The mucous membrane, however, tends to evert with this suture, and the mesenteric border is particularly weak. The suture of the mucous membrane could not be depended upon to prevent leakage into the triangular space formed by the mesentery. A specimen was exhibited to show how much union might take place after an end-to-end anastomosis done only nine hours before death. The specimen emphasized the importance of bringing the intestinal wall firmly against the peritoneal covering. He believed that an inner row of sutures going through all of the coats of the intestine, and reinforced by a row of Lembert's sutures would afford the best results. Personally, he did not feel that it was safe to leave a row of through-and-through sutures in the intestine unless reinforced by a row of Lembert's sutures. It could not be doubted that the mucous layer of the intestine is frequently pierced in the effort to pass a suture only through the

thin submucous layer, and yet no serious results follow. It had been found by actual experiment that the Maunsell suture, reinforced by the Lembert suture, gives practically no diaphragm formation in the bowel. The method advocated by the speaker was in effect the same as this, though done somewhat differently. So far as he had been able to ascertain, the method which he advocated was original with him.

Dr. ROBERT ABBÉ said that he had learned that no one method was applicable to all cases. In the majority he had preferred to use the Murphy button, though he was free to say that he had achieved no such results as were implied in the statistics collected by Murphy's assistant. Certain modifications in the use of this button were useful, such, for example, as slipping it within the bowel and pressing the parts together so as to punch out a portion of the bowel and give rise subsequently to an annular necrosis. The weight of the Murphy button, tending to produce kinking of the bowel, the occasional occlusion of the lumen of the button, and its retention were certainly serious disadvantages. The union of two ends of the intestine was the method which surgeons would eventually employ in a large proportion of cases. It was most important that the entire inner coat of the bowel should be grasped in the inner suture, as this would secure fixation of the bowel and insure good union. The question of the diaphragm made by this suture seemed to him of decidedly minor importance, although Murphy seemed disposed to magnify it. In the future, if the patient's condition warranted it, he would again adopt this revival of the old method of end-to-end suture. The plastic exudate formed in from twenty-four to forty-eight hours is usually sufficient to protect and close the parts. He wished to congratulate Dr. Dowd on the excellent result attained in the desperate case of gangrenous intussusception.

Dr. LILIENTHAL said that he now practically uses the Murphy button only in gastroenterostomy. He had already published a method of intestinal suture precisely similar to the one described by Dr. Dowd. Laplace's clamps seemed to him wholly unnecessary.

Dr. JOSEPH A. BLAKE said that he believed the best method of intestinal suture was by means of a suture passing through all of the coats, and then reinforced with another. The result in Dr. Dowd's case was a most excellent one.

Dr. CARL BECK said that he, too, thought surgeons would come back to the use of the intestinal suture. It had been his good fortune to see Czerny operate upon the first undisputed successful case of intestinal suture. The speaker said that he had made some experiments on cats, and had published them in *Langenbeck's Archives* in 1879. In some of these animals, resection and intestinal suture had been employed, while in others an artificial anus had been established. It had been found that greater success had followed the use of the former plan.

Dr. DOWD said, that after looking over the illustrations of the method published by Dr. Lilienthal, he saw that it was practically the same method of suture as that which he had himself worked out and had advocated in his paper. It was a great gratification to him to find that those present were so generally in favor of intestinal suture.

Acute Pancreatitis, with a Report of Three Cases.—Dr. GEORGE WOOLSEY read this paper. He said that formerly, for some unknown reason, the classification of pancreatic inflammation had been different from that employed for inflammation elsewhere. In acute cases, leading to sudden death, hemorrhage was a prominent feature. It was still uncertain whether this hemorrhage is primary or secondary to the inflammation. Besides the hemorrhages, a hemorrhagic similar to that observed in cholæmia was present in acute pancreatitis. Acute pancreatitis was often associated with fat necrosis, and was essentially due to the interference with the discharge of the pancreatic secretion, and to its escape into the tissues. Lesions of, or near, the pancreas had been found experimentally to lead to necrosis of that organ. A localized abscess might occur in or about the pancreas, with or without necrosis of the pancreas itself. The cases reported in the paper threw little light upon the etiology farther than to show that alcoholism may be an important factor. None of these cases gave a history of previous injury. Severe cramp-like pain, distention of the colon, vomiting, and irregular temperature were the common symptoms, and if associated, as was sometimes the case, with constipation, might lead to an error in diagnosis. The diagnosis was almost always difficult. The sudden onset and collapse, and the abdominal distention in connection with the history of injury, alcoholism, or biliary colic, sometimes allowed of making a probable diagnosis, but most cases were not determined before operation. In all three of the cases reported, the pancreas was hard and enlarged. Diminution of the ethereal salts in the urine had been demonstrated to be an unreliable sign, but glycosuria afforded useful confirmatory evidence. Where the diagnosis was clear, some authors had recommended the use of the posterior as well as the anterior incision, the former being made at the costo-vertebral angle. The prognosis was bad in all cases of pancreatitis, but was worse in acute hemorrhagic pancreatitis, and best where there is a localized abscess. Recovery without operation was almost out of the question.

The first case reported was that of a woman of twenty-three years, who looked ill and septic. The greatest tenderness had been in the region of the vermiform appendix. Several ounces of dark fluid had been evacuated at the operation, and the gall-bladder found distended. There were several small spots of fat necrosis on the peritoneum, and in the region of the pancreas two or three necrotic patches. On admission, the leucocyte count had been 39,000, whereas a week after operation it had been 15,000. The patient had left the hospital after nineteen days. The second case was that of a man of fifty-two, giving an alcoholic history. His illness had begun with a chill the night before admission, and the next morning there had been vomiting, abdominal distention, and abdominal cramps. He had been operated upon the same day through a three-inch incision above the umbilicus. The pancreas was hard and enlarged, especially at its head. The temperature ran up to 104° and the pulse to 140 for the first four days, and two saline infusions were required. His recovery was largely attributable to the free use of whiskey, which seemed favorably to influence his restlessness and delirium better than anything else. The urine contained a little albumin, but no sugar. Very large nonpathogenic cocci had been found in the fluid from the peritoneal cavity.

The third case was that of a man, twenty-nine years of age, a truckman by occupation. He had been admitted on July 27, 1901, and gave a history of excessive use of tobacco and spirits. The present attack had followed a debauch. The vomiting was greenish, and the bowels moved regularly, but the stools contained no free fat. The urine contained some sugar. As the symptoms had improved at first, no operation had been undertaken immediately. Finally, however, the symptoms of septic peritonitis had developed, and the patient had then been promptly operated upon through an incision in the median line above the umbilicus. There was a walled-off abscess in the pelvis in which the appendix was found. The adhesions were broken up, and the cavity thoroughly flushed out. For a few days after the operation there had been some vomiting of a brownish fluid. The bowels had moved freely on the third day, and for two weeks thereafter there had been a profuse diarrhœa. When discharged from the hospital, in September, his general condition had been much improved.

Dr. CHARLES N. DOWD said that Halsted had recently

published a case of acute hemorrhagic pancreatitis in which there had been obstruction of the gall-duct, thus leading to a retroinjection of the bile into the pancreas. Opie had performed some experiments on animals which seemed to point to this retroinjection of bile as one of the causes of acute hemorrhagic pancreatitis.

Dr. Abbé said that he had had no case in which he had recognized fat necrosis during operation. Three cases of pancreatic cyst, secondary to inflammation, he had drained with good result. Nine years ago he had seen a gentleman who had been steadily losing health for about six months before an epigastric tumor had been discovered. On exploratory operation, a large, hard, and solid tumor had been found in the head of the pancreas, and had been mistaken for a cancer. In order to relieve him, an anastomosis had been established between the gall-bladder and the colon, and to his surprise the man's health had been completely restored. Dr. Abbé said that he had examined this man only about a year ago, and had found no evidence at that time of the former trouble; hence it could not have been a malignant growth. The case was very instructive, because it seemed as if this man's life had been saved by relieving the pressure of bile.

Dr. Benjamin T. Tilton said that he had recently observed a case of acute hemorrhagic pancreatitis which had shown all the usual signs of this affection, together with those of intestinal obstruction. He had operated, and had found a large quantity of hemorrhagic fluid in the peritoneal cavity, but no evidence of fat necrosis. At the autopsy the pancreas had been found small and infiltrated with blood, and there was a fat necrosis in the adjacent omentum and mesentery. The man was decidedly alcoholic. The condition of the gall-bladder in Dr. Abbé's case was probably the result of hyperplasia of the head of the pancreas, and consequent pressure and stagnation of bile.

Dr. Joseph Wiener said that the disease under discussion is quite obscure. The therapy employed in the cases reported in the paper seemed to be identical with that considered appropriate for peritonitis. In the second case reported it seemed to him not at all improbable that the drainage used had actually drained the pancreas.

Dr. Woolsey said that the experiments of Opie, though very interesting and instructive, did not seem to explain all the cases of pancreatitis. Dr. Abbé's case would probably come under the heading of subacute pancreatitis, a class of cases not very uncommon, and often leading by pressure to gallstone formation. Pancreatitis with acute invasion does not necessarily involve hemorrhage, necrosis, or abscess. In the second case, there had been pancreatic fluid free in the peritoneal cavity, and a peritonitis of more or less obscure origin, though it was known that peritonitis is often associated with pancreatitis. In the last case there had been no fat necrosis.

Orchidectomy for Torsion of the Spermatic Cord.—Dr. Joseph Wiener presented this specimen, which had been taken from a boy of fifteen, who, five days previously, had lifted a heavy weight. He complained of pain in the right groin and lower part of the abdomen, accompanied by fever and restlessness. There was a swelling in the right groin about the size of a hazel nut. The pulse was 84 and the temperature 101°. The right side of the scrotum was red and œdematous. In the upper portion of the scrotum and in the inguinal canal was a swelling, about the size of a hen's egg. The case was supposed to be one of strangulated hernia. On opening the tunica vaginalis, a considerable quantity of bloody fluid was found. Inside was a tumor about the size of a small lemon, which proved to be the testicle and epididymis. About one inch outside of the external ring, the spermatic cord was found twisted, and as the circulation could not be restored, the testicle was removed.

Orchidectomy for Syphilis.—Dr. Wiener also presented this specimen, which had been taken from a man, fifty-six years of age. He denied syphilis. For seven weeks previous to admission, he had noticed a swelling of one testicle. He also had profuse expectoration, but examination failed to show any tubercle bacilli. The testis and epididymis were removed under local anæsthesia, and Dr. Mandlebaum examined the specimen and reported it to be syphilis of the testis. According to authorities in pathology, it was impossible to differentiate between syphilis and tuberculosis of the testis except by microscopical examination.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, December 12, 1901.

William L. Stowell, M.D., Chairman.

Malnutrition.—This was the general topic for the evening's discussion, and it was considered under the following heads:

Syphilis.—Dr. C. G. Kerley read this paper. He said that according to his observation the severity of the disease in the offspring corresponds to, and is dependent upon, the activity of the disease in the parent. A severe infection results in sterility or death of the fœtus; with a lesser degree the child may show no evidence of the disease until some time after birth. One can never promise the man or woman who has had syphilis that their children will be free from syphilis. Syphilis is a cause of malnutrition in the early months of life, but it differs in many respects from the malnutrition associated with various other disorders, and hence it is not of special diagnostic value. In children varying in age from three years to puberty, the persistence of malnutrition in spite of good treatment was strongly suggestive of syphilis. Two cases were cited to show how debility and malnutrition might be present after months of treatment by different physicians according to the most approved methods, and yet rapidly disappear under the use of mercury and iodide. In one of these cases the father had finally confessed to having had syphilis fifteen years before marriage. He said that he had received good treatment, and had been told that he was thoroughly cured and might safely marry. Children who are under size and under weight, who are easily tired and show a lowered vitality, should be given the benefit of a course of specific treatment regardless of the statements or social position of the parents.

Tuberculosis.—Dr. Floyd M. Crandall took up this part of the subject. He called attention to the fact that tuberculosis is one of the most protean of diseases in its manifestations. The anæmia accompanying tuberculosis is usually marked by a diminution of the red blood corpuscles and of the hæmoglobin; it is secondary and not due to disease of the blood-making organs. The author gave special attention to the concealed forms of tuberculosis in children. He said that children sometimes waste away and die without showing signs of any organic lesion. They seem to be suffering from simple marasmus, yet at autopsy tuberculous lesions are discovered. In other cases, after the symptoms of marasmus have existed for a greater or less period, the signs of organic disease develop, usually in the lungs. It was because of the existence of such cases that the theory of a "pretuberculous" stage had been propounded. This so-called pretuberculous stage was probably nothing more than an early stage of tuberculosis in which the disease had not yet been recognized. The deeper lymph nodes were the most common seat of concealed tuberculosis. These nodes may be seriously affected without involving the superficial nodes. On the other hand, involvement of the superficial nodes without constitutional disturbance affords no evidence of involvement of the deeper nodes. The anæmia of tuberculosis was certainly not characteristic of the disease. Loss of weight was common, but did not necessarily proceed steadily. Ca-

chexia rarely occurs early enough or is sufficiently distinctive to be of value in making the diagnosis before other symptoms can be recognized. An absence of cough in tuberculosis was by no means uncommon; even with pulmonary involvement it might occur rather late, and be so slight and at such long intervals as to be entirely overlooked by the physician. Sometimes it is of a paroxysmal character, simulating pertussis. Marked fever may not be present until late in the disease. The indigestion, loss of appetite, and vomiting so often seen in these cases were by no means characteristic. There was a type of tuberculosis in children resembling typhoid fever. In this type, wasting in the first stage, and wasting and fever in the second stage, were never absent. Unfortunately, even after pulmonary signs had developed, it was not possible to be too dogmatic in one's statements, for such symptoms are sometimes met with in pure marasmus. While none of the symptoms are characteristic of tuberculosis, taken together they form a group which should place the physician on his guard, and lead to a timely diagnosis. Anæmia and wasting in a young child, in whom thorough examination fails to show an adequate cause, should always lead to a suspicion of incipient tuberculosis. In tuberculous families, children between the ages of fourteen and twenty should receive special care, and any anæmia should receive prompt and careful treatment. He had come to look upon chlorosis as a much more serious disorder than is generally supposed. A chlorotic girl is a candidate for almost any wasting or infectious disease, and foremost among such diseases should be placed tuberculosis.

Rachitis.—Dr. A. JACOBI made some remarks on this subject. He said that in connection with malnutrition of rachitis one should differentiate between malnutrition occurring in a rachitic child, and malnutrition dependent upon rachitis. Symptoms of starvation and of atrophy were present in rachitis, but also in other conditions. There might be a deficiency of lime in the bones of rachitic children, but also in other conditions. Disordered nerve action could not be considered as one of the principal causes of rachitis, though it occurs in this disease as well as in others. The causes generally given for rachitis were found in a number of other disorders. While many cases of rachitis could be traced back to hereditary syphilis, there were a great many more cases of hereditary syphilis that had nothing whatever to do with rachitis. Artificial alimentation was justly given as a cause of rachitis, yet it also led to many other diseased states. There were really only a few forms of malnutrition which give rise directly to rachitis. These were a moderate excess of lactic acid in the stomach and the absence of hydrochloric acid. The absence of hydrochloric acid would certainly lead to an absence of lime and a diminished supply to the bone. The absence of lime alone was not sufficient to constitute rachitis. Rachitis had generally been studied in the bones, and here it showed itself either as an epiphysitis, with considerable swelling of the epiphysis, or as soft deposits on the periosteum, or as an absorption of the interior portion of what had been previously normal bone. The last gives rise to a process resembling osteomyelitis in appearance, and results in deformities which are apt to be permanent. The part of the body which suffers most, and gives rise to malnutrition, is the chest. First, the chest loses its elliptical shape, and in this way interferes with the action of both the lungs and the heart. Where scoliosis was also present, as was frequently the case, the aorta was drawn out and distorted so as to interfere with the circulation in this great vessel. The thymus gland was apt to be unusually large in rachitic babies, and the space between the vertebræ and the manubrium was thereby narrowed. Even with a moderate amount of chest compression these children appear to have enlargement of the liver and spleen, because of the downward displacement of these viscera. The blood had been studied in connection with rachitis. Jaksch found less salts present, while Schiff found less hæmoglobin and the normal amount of red cells. John Lovett Morse, on the other hand, had been unable to find any characteristic changes in the blood. It was evident, therefore, that rachitis is not a disease of the bones alone, but a constitutional disease. It often manifests itself almost wholly in the muscles. The striped muscles may be so much affected as to give rise to a form of debility so marked as to have led to the improper designation "pseudoparalysis." The intestinal muscles share in this weakness. When a breast-fed infant that was not constipated at birth becomes so in the second or third month, one may feel pretty sure that rachitis is present. Because of the weakness of the muscles there is a tendency to pulmonary atelectasis and bronchial catarrh, and the latter is the original cause of the enlargement of the lymph bodies, beginning with those of the mediastinum, and finally extending all over the body. The liver is frequently large, and is apt to exhibit fatty degeneration. The infectious theory of rachitis had been first suggested by Oppenheimer of Heidelberg, because of the restlessness at night and the enlargement of the spleen. The digestive organs share in the malnutrition, and hence tympanites, colic, and vomiting may be present. Rachitis of the base of the cranium frequently begins in intrauterine life, and is the cause and anatomical explanation of many cases of cretinism. This shortness of the base of the cranium arises from an early ossification of the synchondrosis between the occipital and the sphenoid bones, and when this synchondrosis becomes ossified, further growth cannot take place. Thus, the large basal ganglia are considerably damaged. Such a cranium is always the seat of hyperæmia and œdema. Laryngismus stridulus in forty-nine cases out of fifty is the result of cranial rachitis. It was evident, therefore, that there are many forms of malnutrition which are directly dependent upon rachitis.

Dr. WILLIAM HENRY PORTER opened the discussion on malnutrition. In his opinion, all forms of malnutrition take their point of deviation from: (1) Defective quantity or quality of food; (2) A lack of a proper amount of exercise, or (3) From conditions disturbing the nervous mechanism. In every case of malnutrition, he thought, one or more of these factors were at work, and each case should consequently be analyzed with reference to these elements. It was only when the health had been deteriorated in one of these ways that a suitable soil would be found for the reception of the germs of the various infectious diseases. Our treatment, therefore, should be directed toward correcting these fundamental conditions.

Dr. WALTER LESTER CARR said that he had been interested in some cases of congenital syphilis in which malnutrition had been a very marked feature. In the first case, there had been marked evidence of direct inheritance. The child had been kept on the breast and had nevertheless lost weight. It had seemed to him that the first thing demanding attention was the improvement of the nutrition. Owing to the diseased condition of the nose the child could not suckle properly; hence his first step had been to have the milk drawn out of the breast and fed to the infant. This had resulted very satisfactorily, and it emphasized the importance of looking into the associated states, and not merely directing treatment to the one underlying disease.

The Nursing of Syphilitic Infants by the Mother.—Dr. JOSEPH E. WINTERS said that recently, in a conversation with a distinguished teacher on venereal diseases, he learned that this gentleman was teaching his classes that infants with inherited syphilis, who are at the breast of an apparently healthy mother, should be weaned. He thought this notion had long ago been abandoned—indeed, he did not think there was any statement in the textbooks warranting such a belief. Many foreign writers state that a majority of cases of inherited

syphilis die, yet the speaker said he had seen a great many of these cases at the Demilt Dispensary, all of them breast-fed. He could not recall that one of them had died. Two had been in one family, and had congenital syphilis, in contradistinction to inherited syphilis. Both of them are living and well to-day. The large mortality from inherited syphilis abroad was probably dependent upon feeding them artificially. The great advantage of breast-feeding, aside from the easy assimilation of such milk, was that the infant could be treated through the mother. He did not rely upon this alone, as a rule; but if the administration of mercurials to the baby disturbs digestion, these remedies should be discontinued and the medication kept up through the mother. There was no danger of the mother inheriting syphilis because she must have already had it before giving birth to the infant.

Dr. David Bovaird, Jr., said that he had seen a case of congenital syphilis occuring at the New York Foundling Hospital in the service of the late Dr. Joseph O'Dwyer, and this physician had directed that the child be taken at once from the mother for fear she might become infected. Dr. O'Dwyer insisted that he had seen syphilitic infants infect apparently healthy mothers, and produce syphilitic lesions in the mother. He mentioned this case because of the high standing of Dr. O'Dwyer as a clinician, though he had no personal experience to support this notion.

Dr. Winters said that in 1837 David Colles of Dublin had first called attention to the fact that there was no case on record of a syphilitic infant having infected its mother and caused a syphilitic lesion. Jonathan Hutchinson had comparatively recently called attention to this same law, and had supported this position by careful investigation, including correspondence with observers in all parts of the world. A number of other prominent clinicians took the same ground, and hence if any physician had himself observed a syphilitic lesion on the nipple of a mother nursing a syphilitic infant, it was his duty to report the case. Dr Winters said that in a large personal experience he had never seen such infection occur. In his opinion, it was not possible for a mother to give birth to a syphilitic infant without having syphilis, for, if she did not get the disease from the father before conception, she must have contracted it during gestation.

Dr. Kerley said that a physician in Munich had reported ten or twelve years ago a case in which such an infection had occurred.

Dr. A. Jacobi said that when a baby is born to a syphilitic father and mother, the father almost always being the guilty one, the baby does not infect the mother, but may infect the wet nurse. It was, of course, criminal to put a baby with hereditary syphilis to the breast of a healthy wet nurse without letting her know what she must expect. It was a law that such a baby does not infect its own mother, probably because the mother has been rendered immune, nevertheless there were some exceptions. He had himself seen some of these exceptions, and had spoken of them, one of these cases being reported by him in the "Twentieth Century Practice of Medicine." These cases were, however, so exceptional that they "proved the rule," and he agreed with Dr. Winters that a syphilitic baby should nurse from its mother, although the mother should be carefully watched and should be warned of the possible though not probable danger.

Puny Children and Specific Medication.—Regarding children who are well enough developed, yet lack in muscle, bone, and general vitality, Dr. Jacobi said that unless treated correctly they would rarely amount to anything. They were most commonly found in well-to-do families, and though given the benefit of change of air and the best of food, they would not thrive until given anti-syphilitic treatment. It was often necessary to repeat this medication at intervals for a number of years, or up to puberty. He had observed this again and again, and had come to the conclusion that probably one of the reasons why our ancestors gave calomel in every disease of childhood was that they had discovered that puny children who do not thrive on ordinary tonics do well on small and frequently repeated doses of calomel. Cases of so-called retarded syphilis were really not retarded syphilis, but examples of syphilis appearing in childhood, and being suppressed by treatment, only to reappear years afterward, perhaps not until the age of twenty or thirty. This later development could be prevented if the treatment in childhood were persisted in for at least a year, and the child were brought for inspection at intervals of a year or two.

Dr. William L. Stowell said that one occasionally met with children having congenital syphilis, who, when grown up, show no evidence of the disease, and have healthy offspring.

Dr. H. D. Chapin said that sometimes syphilitic babies are well nourished, and even stout, though presenting a mucous patch or some other evidence of their constitutional dyscrasia.

Medical Items.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended December 21, 1901:

SMALLPOX—UNITED STATES.

	CASES.	DEATHS.	
California, San Francisco	Dec. 1-8	1	
Georgia, Elberton	Dec. 12	12	
Indiana, Evansville	Dec. 7-14	3
